The variety of shapes, sizes, and relative abundances of microbial food items has driven the evolution of a comprehensive suite of methods to capture them and a considerable diversification of protozoan morphologies. In general, the size of a protozoon relative to its prey dictates the most efficient food-capturing mechanism. Where the predator is typically much larger than its prey, filter-feeding prevails, and where the size difference is less the protozoon is more likely to be a raptorial feeder – One that seeks out relatively large individual food items. Thus, the planktonic choanoflagellate feeding on a dilute suspension of tiny bacteria 20 times smaller than itself does so with a very fine filter, and the ciliate feeding on dinoflagellates half of its size seeks out and captures each one individually. There are, of course, many exceptions, such as the marine heterotrophic dinoflagellates that use a feeding veil to trap and digest diatoms much larger than themselves.

The third main feeding type in protozoa is termed “diffusion feeding.” This is particularly common in planktonic ameboid protozoa (radiolarians, foraminiferans, and heliozoans) and in the suctorian ciliates. It works when prey items collide with the sticky spines, tentacles, or axopods that radiate from the protozoon. Unlike the other two main modes of feeding, the protozoon simply waits for the arrival of its prey, much as a spider waits for an insect to be snared in its web.

Thus, there is a close link between protozoan morphology (especially of the food-capturing organelles) and the way in which a protozoon functions as a grazer. Therefore, when the authors classify the free-living protozoa into broad morphological groups, they are simultaneously allocated to broad functional groups. The three broadest morphological–functional groups are the ameboid, the flagellated, and the ciliated protozoa, and each has its own strengths as a phagotroph. Representatives of all three may feed on the same type of microbes in the same place (e.g., in an aquatic sediment), but they will differ in the mechanics and efficiency of capture of any particular food particle. A filter-feeding flagellate will have a relatively large filter area, a high volume-specific clearance and competitive superiority over filter-feeding ciliates when grazing on planktonic bacteria. A helioflagellate and a suctorian ciliate will both practice diffusion feeding, but the former will be adapted for snaring bacteria, whereas a diffusion-feeding suctorian will specialize in trapping flagellates and ciliates.

Many protozoa are microaerophilic: They seek out habitats with a low level of dissolved oxygen that is just sufficient to drive their aerobic respiration and low enough to exclude metazoan competitors and predators. Microaerobic habitats are common in aquatic sediments and in oceanic oxygen minimum zones. These are zones in which the raw materials for microbial growth arrive from opposite directions (e.g., where oxygen and light arriving from above meet carbon dioxide and sulfide from below) and in which there is therefore an elevated abundance of microbial food. Therefore, microaerophily is an adaptive behavior: It brings protozoa into contact with high abundances of microbial food. It also stimulates the growth of nutritional symbionts such as sulfide-oxidizing bacteria and endosymbiotic algae. Many microaerophilic protozoa are also temporary anaerobes, but unlike the true anaerobes that live permanently in the absence of oxygen, their metabolism is fundamentally aerobic. The true anaerobes – Those that complete their entire life cycle in the absence of oxygen – Live principally in aquatic sediments. There are many species, but none is ever abundant. Most use hydrogen-evolving fermentations for energy generation, and the hydrogen is used by anaerobic bacteria, especially endosymbiotic methanogens. Thus, methane is released from these protozoan consortia. The anaerobic protozoa are probably the only phagotrophic organisms capable of living permanently in the absence of dissolved oxygen (Fenchel and Finlay, 1995) (with perhaps the exception of species of the metazoan phylum *Loricifera* - see Danovaro et al., 2010).

The real diversity of symbiotic associations involving protozoa is insufficiently known. In some cases, complex interactive behaviors have evolved between the partners. In the marine, sand-dwelling ciliate *Kentrophoros*, the entire dorsal surface of the ciliate is a coat of sulfide-oxidizing bacteria that can grow only in the narrow layer within the sediment where oxygen and sulfide overlap. The ciliate host's innate microaerobic behavior enables it to seek out the habitat that the symbiotic bacteria need for growth. The ciliate then invaginates its dorsal surface and digests the bacteria because it does not have a mouth, and this is its only source of nutrition.

It is clear that many of these symbiotic consortia involving protozoa represent tightly integrated functional units; indeed, the symbionts may be almost as deeply embedded functionally in the consortium as the protozoon's other organelles. Two points must be noted. First, it is the combined phenotype of the consortium, rather than that of any individual consortium partners, on which natural selection will operate, and there are examples of how the fitness of a protozoon in a particular habitat can be improved by the acquisition of endosymbionts (e.g., the algal symbionts of ciliates living in the metalimnia of freshwater lakes). Second, the biodiversity of protozoa, when quantified simply in terms of protozoan species richness, will fail to take account of the large supplementary microbial diversity with which the protozoa are necessarily associated.

Therefore, the diversity of free-living protozoa may be classified into broad morphological–functional groups: ameboid, flagellated, and ciliated protozoa. Almost any free-living protozoon can be placed without difficulty in one of these groups. It must be stressed, however, that these groups are not concordant with any system of classification of protozoa published in recent years; nor are they in most cases aligned with the independent lineages that are emerging in the molecular phylogenies (e.g., those based on sequence variation in ribosomal RNAs) which reflect the main episodes in the history of eukaryotic evolution. Heterotrophic flagellate groups, such as the diplomonads and trichomonads, appear in the early emerging lineages, but other flagellates (e.g., choanoflagellates, chrysomonads, dinoflagellates, and haptomonads) are classified within recently diverging lineages. The ameboid protozoa too are scattered across many lineages. The naked amebae without mitochondria (the pelobionts) diverge early and close to the diplomonads, whereas the vahlkampfiids, slime molds, and various other groups of naked and testate amebae appear in other independent lineages that are evolutionarily quite distant from each other. The morphological–functional group of the ciliates is the only one which remains intact, as a monophyletic group, in current molecular phylogenies.

The process of distilling the vast quantity of molecular information generated in recent years has generated some entirely new phyletic assemblages, including the stramenopiles, a group containing organisms as morphologically and functionally dissimilar as

chrysomonad flagellates and diatoms, and the alveolates – A group that embraces the dinoflagellates, the ciliates, and a large group of exclusively intracellular parasites (the apicomplexans) (Adl et al., 2012). In the next section, the authors focus on the broad morphological–functional groups of free-living protozoa, define what is meant by species, and quantify the species within these groups.

The Nature of Protozoan Species

There is no universal agreement on what constitutes a protozoan species. The most widely used concept is the morphospecies because it is relatively easy to discriminate a great diversity of protozoa using body form alone. This concept is especially useful because morphology is closely related to the ecological function. In many free-living protozoa, the structure of the feeding apparatus and the size and shape of the cell determine how the protozoon functions in the natural environment; therefore, the cell form largely determines the ecological niche that the protozoon occupies. Discriminating species on the basis of form might then be equivalent to discriminating them according to the ecological niches they occupy. We could say that if a protozoon looks the same in different places, then it is the same in different places. However, there are problems with such a simple concept. It is known that a morphospecies can be composed of ecologically distinct populations, such as those adapted for maximum growth rate at different temperatures. Therefore, although it is possible to collect apparently identical representatives of a morphospecies in different corners of the world, and one might be encouraged by the belief that they were filling exactly the same niche in these different places, in reality they could be phenotypically quite different. The same problem applies with respect to genetic differences. It is possible to find genetic differences, especially sequence differences in ribosomal RNAs, in morphologically identical isolates collected from different places. The significance of these genetic differences is not known; nor is it known if genetic and phenotypic divergence are correlated. It appears, however, that there is no correlation between genetic divergence and geographic distance.

Protozoa spend most of their time as asexual organisms, but some do reproduce sexually, if only periodically, and in some well-studied cases (e.g., the ciliate genera *Tetrahymena* and *Paramecium*) morphologically indistinguishable biological species (reproductively isolated gene pools, also known as sibling species) have been studied thoroughly. Different sibling species within a morphospecies may be genetically identical to each other or extremely divergent (at least with respect to ribosomal RNAs), and there is no apparent correlation between genetic isolation and genetic divergence. Again, there is no good evidence for biogeography of protozoan sibling species, and members of the same sibling species can be found on different continents. It is possible that sibling species carry unique phenotypic traits that equip each species for a particular niche, but this has not been demonstrated. The real problem in using a biological species concept for protozoa is that it is not practical for all but a few easily cultivated protozoa. The majority of protozoan species have never been cultivated, and neither the frequency nor the character of their sexual behavior (if any) are known or are ever likely to be known. Most people who study protozoa in the natural environment use the morphospecies concept because it is practical, it embodies the close link between form and function, and it is the morphospecies that fills the niche, if not always the minutest niches, that can be discerned by the human observer. The morphospecies may contain much genetic variation and be capable of expressing a wealth of phenotypic variation, but it is the best tool that is available for ordering the diversity that lies within the protozoa.

One problem that is particularly acute when dealing with organisms the size of protozoa is that the quality of one's perception of morphology is very definitely a function of the tools that are available (Mitchell and Meisterfeld, 2005). Thus, better tools (e.g., quality microscopes) enable the discrimination of finer detail. The logical extension of this is that even individual protozoa in a population might be discriminated one from the other and could therefore be referred to as separate morphospecies. Modern optics have undoubtedly lent impetus to the business of describing many new species, some of which are undoubtedly legitimate, whereas many have been established on morphological criteria that are trivial or have no conceivable functional significance.

An additional problem with the morphospecies is that it is often difficult to decide exactly where a species begins and ends. Although most observations are made of the vast number of individuals that cluster around the central tendency of any population, the individuals at the tail ends of the distributions abut and often overlap those of other species. Morphological variation then appears to be continuous across many species. Examples of this have been described: In some of the large spongiöse spumellarian radiolarians, the major features (e.g., skeletal and cytoplasmic morphology) that are used to discriminate species intergrade to such an extent that it is not possible to unambiguously ascribe individual radiolarians to nominal species.

However, the evolutionary process in radiolarians and other protozoa probably works in the same way as it does for other organisms such that it maintains phenotypically discrete species in niche space that is essentially continuously variable. The phenotypic traits that sustain these discrete species in protozoa are presumably quite diverse in character and possibly not totally comprehensible. Among the more accessible of these traits are the morphological characters that the authors use to separate species. However, the likely limitation of these is that they enable us to perceive only the fairly coarsely resolved, sometimes overlapping entities that we call morphospecies.

Protozoa and Ecosystem Function

Protozoa are abundant. One gram of soil typically contains 103–107 naked amebae, 105 planktonic foraminiferans can often exist beneath 1 m² of oceanic water, and almost every milliliter of fresh water or sea-water on the planet supports at least 100

heterotrophic flagellates. When expressed in global terms, these numbers are very large, and an inevitable consequence of the persistence of such a large number of very small organisms is that migration rates will be relatively high. It follows that rates of speciation and extinction must be low, as will the consequent global number of species. It also follows that free-living protozoa are unlikely to have biogeographies, and endemic species probably do not exist. The authors might expect that the local diversity of protozoa would account for a significant proportion of global diversity, even if at any moment in time much of this diversity is represented by rare or inactive individuals (e.g., cysts awaiting the arrival of suitable conditions). There is indeed good evidence for the global distribution of protozoan species, including the morphologically distinctive flagellate *Rhynchomonas nasuta* that has been found in most aquatic and terrestrial environments worldwide; marine foraminiferans and ciliates found living in slightly salty water of desert oases, hundreds of kilometers from marine coasts; the same radiolarian species living in high northern and southern oceanic latitudes; the same pond-dwelling ciliates living in Australia and northern Europe; and the cosmopolitan distribution of the same species of agglutinated foraminiferans in the deep-sea benthos. In general, protozoan morphospecies are ubiquitous and apparently cosmopolitan if the habitats to which they are adapted are distributed in different parts of the world (Finlay, 1998, 2002). In accordance with this, the global number of protozoan species is indeed relatively modest (Table 1), and the number of species that can be retrieved from a local area (e.g., a pond), in both active form and from a passive state is a significant proportion (usually at least 10% for various morphological-functional groups) of the global total. This fact may not be obvious from short-term ecological sampling programs because only a limited number of microbial niches are available at any moment in time.

Protozoa and other microorganisms have other special properties. Microbial activities interact strongly with physical and chemical factors in the natural aquatic environment (e.g., light transmission or the concentrations of essential nutrients) to create a continuous turnover of microbial niches. These niches are quickly filled from the locally available diversity of rare and dormant microbes, and the activities of the latter create further reciprocal interactions. Therefore, the diversity of active protozoan species in a pond, at any moment in time, is the result of preceding reciprocal interactions involving many biological and nonbiological factors, and the biodiversity of protozoa and other microbes is an integral part of ecosystem functions such as carbon fixation and nutrient cycling (Finlay et al., 1997).

Table 1 Estimates of global species richness of extant free-living protozoa^a

			Marine	Nonmarine	Total
Ameboid protozoa	Slime molds	Dictyostelids	—	60	60
		Myxomycetes	—	550	550
	Rhizopod amebae	Naked	180	220	400
		Testate	—	200	200
	Foraminiferans	Planktonic	40	—	40
		Benthic, inshore	4000 ^b	—	4000
		Benthic, deep sea	250 ^b	—	250
	Actinopod amebae	Acantharians	150	—	150
		Radiolarians, solitary	750	—	750
		Radiolarians, colonial	50	—	50
Heliozonas		—	120	120	
Flagellated protozoa		Excluding heterotrophic dinoflagellates ^c	Marine plankton	420	—
	Marine benthos		330	—	330
	Freshwater and soil		—	350	350
	Heterotrophic dinoflagellates	900	110	1010 ^d	
	Other mixotrophic flagellates	—	—	150 ^e	
Ciliated protozoa		1400	1660	3060	
Total				11,890	

^aCompiled from numerous published and unpublished sources. The more problematic estimates are highlighted.

^bThere is considerable uncertainty attached to these estimates. The figure of 4000 is generally accepted as a working figure for extant species but is probably inflated by synonyms, especially those of shallow-water benthic species. There is no firm information for species richness of deep-sea benthic foraminiferans (Gooday et al., 1998). The estimate of 250 is approximately double the typical figure for local richness of species, most of which may be cosmopolitan, but there are probably many undescribed deep-sea soft-shelled foraminiferans that have in the past been ignored by geologists.

^cThe total given here for heterotrophic flagellates is 1100 species. This includes some synonyms and mixotrophs. It is believed by some that the real global total is closer to 3000 species.

^dAssuming there are 1800 marine and 220 freshwater species, and that 50% of these are heterotrophs.

^eThis estimate is simply derived by doubling some recent estimates. Note that these species may be only temporarily phagotrophic.

Biological Diversity and Global Species Richness

Ameboid Protozoa

Slime molds may be regarded as protozoa because they spend most of their active lives as amebae or as naked ameboid (and often macroscopic) plasmodia (Fig. 1). They have been known by many names, including mycetozoa ('fungus animals'), because although they never develop hyphae they produce fruiting bodies (sporangia) supported on cellulose-rich stalks. There are two large groups – The cellular slime molds (the dictyostelids, e.g., *Dictyostelium*) and the acellular slime molds (e.g., *Physarum*). Two smaller groups are the acrasids (e.g., *Acrasis*) and the protostelids (e.g., *Cavostelium*). The dictyostelids are typically phagotrophic amebae, but when starved they aggregate, form a migrating slug, and then produce a fruiting body from which spores are released. These later germinate to produce amebae. In the acellular slime molds (*Physarum*), individual amebae (sometimes thousands of them) with or without flagella coalesce to form a distinctive (often brightly colored) multinucleate plasmodium which gives rise to fruiting bodies. Slime molds are common in damp forest soils, tree bark, and dead or dying wood, and abundance and local species richness are greater in deciduous than in coniferous forests. There is extreme patchiness in the distribution of dictyostelid species in forest soils, and coexistence of multiple species in the same small soil samples is rare. Many slime molds species are believed to be cosmopolitan. The phagotrophic ameboid stages of slime molds may be quantitatively important grazers of bacteria, fungi, and the

Fig. 1 A selection from the variety of form and function in ameboid protozoa and slime molds. (1) an actinophryid heliozoon (*Actinophrys*; diameter of about 0.1 mm) ingesting a flagellate; (2) a benthic foraminiferan (*Rotalia*) trapping diatoms and bacteria in its reticulopodial net; (3) a naked ameba (*Ameba*) using pseudopodia to trap a flagellate; (4) a polycystine radiolarian (*Heliosphaera*; spherical body ~0.3 mm) with symbiotic dinoflagellates and an entrapped tintinnid ciliate; (5) polymorphic life cycles of dictyostelid slime molds (e.g., *Polysphondylium*; outer circle) and acellular slime molds (e.g., *Physarum*; inner circle); (6) testate ameba (*Assulina*; ~0.08 mm) with its prey (an algal cell) caught on a sticky filopod.

other primary decomposers of organic matter in soil. Other ecological interactions of slime molds may be at least as complex as their life cycles (e.g., the migrating slugs of dictyostelids appear capable of repelling grazing nematodes).

Rhizopod amebae use pseudopodia for locomotion and feeding. There are two large groups (Fig. 1) – the “naked amebae” (e.g., *Acanthamoeba*, *Vannella*, *Ameba*, and *Vampyrella*) and the shelled “testate amebae” (e.g., *Arcella*, *Nebela*, and *Euglypha*). Most rhizopod amebae feed nonselectively by engulfing diatoms and other algae, unicellular and filamentous cyanobacteria, detritus, and bacteria. However, there are notable variants: *Vampyrella* dissolves a hole in the cell wall of a green alga or desmid and then enters through the hole to digest the cytoplasm of the prey. Some are opportunistic pathogens of man (e.g., in the genera *Acanthamoeba* and *Naegleria*).

Naked amebae occur in the plankton, but these species are usually very small ($<10\ \mu\text{m}$) and typically associated with suspended flocs (e.g., marine snow). However, it is likely that all rhizopod amebae need to be attached to a surface if they are to feed, and much larger numbers are found in aquatic sediments. Amebae are particularly abundant in soils (103–107 per gram dry weight), where together with heterotrophic flagellates they probably control bacterial abundance. A few testate amebae can be planktonic (e.g., *Diffugia*), but most live in soils and in *Sphagnum* bogs. The prey size of testates must be limited by the shell aperture size.

Naked and testate amebae offer different challenges when attempting to identify species. The naked forms are distinguished by the forms of their bodies and pseudopods in locomotion, but many species constantly change shape and the absence of fixed characters often makes it difficult to identify them without resorting to an analysis of ultrastructure. The testates construct tests which have species-specific architectures, but these are often modified according to the nutritional status and local environmental factors, such that the variety of tests described is extraordinarily large and the task of deciding where one nominal species begins and the other ends is at least as difficult as it is for the naked amebae. One practical solution to the problem of identifying living naked amebae in natural samples is to allocate them to one of the several broad morphotypes, e.g., those that extend lobose pseudopodia, slug-like forms with eruptive or noneruptive locomotion, and fan-shaped forms. No clear relationship has been established between morphology and ecological function in naked amebae, although it is likely that the limax (slug-like) amebae are predominantly benthic species.

Some naked amebae (especially those that form extensive anastomosing plasmodial networks) resemble hybrids of shell-free foraminiferans and slime molds. Some can reach several centimeters in diameter. They are typically very slow moving and apparently perfectly adapted for grazing extensive areas of soil surface (*Leptomyxa*) or diatom mats in the marine benthos (*Corallomyxa*). Some free-living naked amebae are anaerobic and do not have mitochondria. As a group, these are referred to as pelobionts, rhizomastigids, archamoebae, or karyoblasteans (e.g., *Mastigamoeba*, *Mastigella*, and *Pelomyxa*). They are relatively common in organically enriched anoxic freshwater and marine sediments. The very large (up to several millimeters in diameter) *Pelomyxa* supports several types of endosymbiotic bacteria, including methanogens, and probably lives exclusively in freshwater sediments. It appears to ingest any organic particles with which it makes contact. It can be locally abundant and the dominant grazer in some anaerobic lake sediments. Most species of naked amebae have been described from fresh waters and soil, and most marine species have been collected from the inshore areas. It is not clear to what extent freshwater species can also live in seawater. Some genera (e.g., *Mayorella* and *Acanthamoeba*) are well represented in both environments.

Foraminiferans live in marine or brackish water environments, and most have calcareous shells (Fig. 1). Cytoplasm emerges through the aperture and pores in the shell to form a repeatedly branching and anastomosing reticulopodial net in which prey are trapped (Lee et al., 2000). The spinose planktonic species (e.g., *Globigerinoides ruber*) have calcareous spines, and familiar Cretaceous chalk deposits (e.g., the white cliffs of Dover, UK) consist largely of the sedimented shells of these species together with the coccoliths of haptomonad flagellates. Some naked amebae that produce similar pseudopodial networks live in fresh waters (e.g., *Biomyxa*) or soil (e.g., *Reticulomyxa*).

The shells of planktonic foraminiferans are generally 0.1–1 mm in diameter, but the pseudopodial network can reach 10 mm and the spines may increase the size to more than 20 mm, making them larger than many marine metazoans. Planktonic species are open-water organisms. They are most abundant in tropical and subtropical waters, in which there is typically one per liter (or $\sim 10\ 5\ \text{m}^{-2}$, depth integrated to 150 m). Each species tolerates only small variations in temperature and salinity, and distinct assemblages of species are associated with five biogeographical provinces – the surface water masses of equivalent temperature on either side of the equator (polar, subpolar, temperate, subtropical, and tropical). However, species in these assemblages are not isolated from each other: Polar species have been recorded in upwelling zones at $10^\circ\ \text{N}$, and species characteristic of high latitudes are also found in the tropics, but in very deep and cool waters.

A typical planktonic foraminiferan produces a mass of reticulopodia (the “halo”) that radiates outward from the shell. This is used to snare prey and to support algal symbionts. Spinose species appear to prefer zooplankton prey, and nonspinose species (e.g., *Globorotalia menardii*) prefer phytoplankton. These preferences may affect the local distribution of species: In the Red Sea north of $20^\circ\ \text{N}$, the dominating spinose species appear to reflect the greater local abundance of zooplankton.

Many planktonic foraminiferans, especially the spinose species (e.g., *G. ruber*), contain algal symbionts that are carried along the spines by cytoplasmic streaming. There are probably only two types of symbionts in planktonic species: the dinoflagellate *Gymnodinium beii*, which is morphologically identical in many host species, and a small yellow-green (chrysomonad-like) symbiont. The symbionts are protected from digestion by the host. The carnivorous foraminiferan *Hastigerina pelagica* envelopes itself in a cytoplasmic bubble capsule which is probably a flotation device but is also used for trapping and digesting prey. *H. pelagica* does not have symbionts but commensal dino flagellates (*Pyrocystis* spp.) that live in the capsule. The role of symbionts and commensals is unclear. High rates of photosynthesis are maintained within the consortium, the symbionts probably transfer significant amounts of fixed carbon to the host, their photosynthetic activity may be necessary for calcification of the host’s shell, and the symbionts may use the host’s (nitrogenous) waste.

Benthic foraminifera have a greater diversity of symbiotic partners, including diatoms (*Nitzschia*), dinoflagellates (*Symbiodinium microadriaticum*), red algae, and chlorophytes (*Chlamydomonas*). Some also sequester chloroplasts from ingested algae. Although many benthic foraminiferan species have been described, information on their life cycles and ecology is available for only about 20 shallow-water species (e.g., *Allogromia*, *Rosalina*, *Spiroculina*, and *Sorites*). These typically drag themselves slowly over surfaces, continually extending reticulopodia to trap prey (diatoms, algae, and bacteria). The abundance of benthic species is correlated with local biological productivity. In the fertile Mississippi Delta, numbers may reach several thousands in an area of 10 cm². Close to sewage outfalls, they are typically very abundant but low in species diversity. The spatial distribution of all benthic species is very patchy. This may be related to asexual reproduction (known only for benthic species) and the consequential limited range of migration of offspring from the parent. Benthic foraminiferans become relatively more important with increasing water depth, possibly due to a competitive advantage they have over metazoans in their ability to rapidly exploit seasonally deposited phytodetritus. In oxygen minimum zones along the continental margins of tropical oceans, they can, because of their relatively small size, tolerate low oxygen conditions better than can metazoans. Also, certain taxa (e.g., *Bolivina* and *Uvigerina*) seem to be adapted for life in oxygen-depleted waters.

Foraminiferans in the deep-sea benthos are often abundant (typically hundreds per 10 cm²) and diverse (species richness may exceed that of nematodes), and they are regarded as major components of the fauna in this zone (Goodey et al., 1998). Because they consume bacteria and detritus, they probably act as a link in the food chain to higher trophic levels in the benthos. Very small species (30–63 µm) are common, but the dominant fauna >500 µm in central oceanic regions (and particularly at depths greater than the carbonate dissolution depth of ~4000 m) are large agglutinated foraminiferans, especially the komokiaceans, which have complex anastomosing networks of tubules. In the benthos underlying the oligotrophic waters of the central North Pacific, the biovolume of komokiacean tests may greatly exceed the biovolume of metazoans. However, the amount of protozoan biomass in komokiacean tests is relatively small, and it may be even less than that of the metazoans that also occupy the test. *Edgertonia floccula* consists of a network of branching agglutinated chambers buried in a large (2–8 mm) inorganic mudball that it shares with cohabiting metazoans. This foraminiferan is one of the most abundant meiobenthic animals in some areas of the abyssal northeast Atlantic. Other deep-sea agglutinated foraminifera (e.g., *Bathysiphon* and *Hyperammina*) may even reach several centimeters in length, and some species stand vertically in the sediment and project into the overlying water, in which they presumably feed. Many of the common deep-sea foraminiferan species are probably cosmopolitan in their distribution.

The xenophyophoreans are another deep-sea group about which relatively little is known. They live in agglutinated, often fragile tests (typically 1–10 cm in length) and they too probably feed on sedimented detritus. Abundances of hundreds per square meter have been reported. The multinucleate protoplasm is enclosed within a labyrinthine organic tube encrusted with foreign particles. The organism also contains numerous crystals of barium sulfate, which have no obvious function. Growth is episodic, with intervening periods of months of inactivity. They have no confirmed fossil record, although they often use the sedimented shells of the planktonic foraminiferan *Globigerina* to strengthen their tests (as in *Homogammina maculosa*).

Foraminiferan fossils are useful for biostratigraphy because (1) their sedimented remains are abundant (e.g., in the “*Globigerina* ooze” which covers much of the abyssal plain beyond the continental shelves), (2) individual shells are identifiable to species level, and (3) their remains allow determination of sea surface paleotemperature. Seawater and calcite differ in their ¹⁸O/¹⁶O ratio. This difference increases with temperature, so the ratio is used to estimate the water temperature at the time the calcite was deposited in the fossil foraminiferan shell. This estimate can then be compared with the established correlation between the temperature of water mass and the extant species it typically supports. Much of this work is supported financially by the oil exploration industry.

Actinopod amebae all have axopods, which are stiffened ray-like pseudopodia that radiate from the cell body (Fig. 1). They also have a peripheral network of filopodia, which are long, thin, sticky pseudopodia used for trapping food organisms that make chance contact. There are three principal groups: (1) Radiolarians, consisting of the polycystines with perforated spiny lattice skeletons of silica and the phaeodareans with skeletons of hollow tubes and spines; (2) acantharians with skeletal spines of strontium sulfate radiating from the center of the organism; and (3) heliozoans, which often lack an internal mineral skeleton (although some species produce skeletal spicules which are either organic or siliceous) and superficially resemble polycystine radiolarians. All actinopod protozoa, apart from a large number of heliozoans, are exclusively planktonic in deep oceanic water.

Radiolarians (Fig. 1) and acantharians range in size from ~30 µm to several millimeters in diameter. Colonial radiolarians (e.g., *Collozoum longiforme*), which occur as gelatinous cylinders with diameters of several centimeters, can reach 3 m in length. Typical food items include diatoms, tintinnids and other ciliates, crustacean larvae, and other zooplankton, all of which are trapped in the peripheral network of axopods and filopodia. The smallest species may eat bacteria (Anderson, 1983; Suzuki, 2015).

Dinoflagellate (*Symbiodinium*), chrysomonad, and prasinomonad symbionts are associated with many polycystine radiolarians. They probably contribute to the host carbon metabolism because the consortium can last many weeks without exogenous food. The symbionts are carried about in the host's cytoplasmic streaming, gathering in the peripheral filopodia at dawn and withdrawing inside the host shell at sunset. The phaeodareans that live near the ocean floor do not have algal symbionts. Radiolarians are found at all water depths down to ~8000 m, although they are most abundant and diverse between 200 and 2000 m (Anderson, 1983). No benthic species are known. Like planktonic foraminiferans, each radiolarian species inhabits an oceanic water mass that lies within a particular temperature range. Moreover, because of the immense depths to which living radiolarians sink, those species living in surface waters at high latitudes are also found in the tropics but in very deep and cool waters. As a consequence, the species assemblages found in surface waters give a misleading impression of radiolarian biogeography. It is believed that radiolarians may be transported in very deep oceanic waters between high northern and high southern latitudes.

Radiolarian abundance and productivity increase in warmer waters. Abundance may be almost nil in the surface waters of the Antarctic, up to 50 m^{-3} in the Caribbean and Gulf Stream, and up to several thousand per m^3 in the Gulf of Mexico. Colonial radiolarians are much less abundant. In the Sargasso they are considered abundant if represented by more than one colony per 100 m^3 . Acantharians can reach relatively high abundances (up to $25\text{--}35 \text{ l}^{-1}$) and they are often the most abundant of the planktonic shelled amebae, but relatively little is known about living organisms because as soon as they are collected the fragile cell membrane breaks and the strontium sulfate skeleton dissolves. Radiolarians are important stratigraphic tools, and skeletal morphology is the main characteristic used to identify species; hence, much information is available on the diversity of radiolarian skeletons.

The heliozoans are predominantly a freshwater group. They resemble functionally the radiolarians, especially with respect to their diffusion feeding. They span a wide size range. Some (e.g., *Actinosphaerium*) can be $>1 \text{ mm}$, but most species are $\sim 40 \text{ }\mu\text{m}$ (*Actinophrys*). Depending on their size, different species feed with little apparent selectivity on algae, flagellates, ciliates, and rotifers. Small heliozoan species account for most of the biomass of ameboid protozoa in the freshwater plankton. Most, however, are attached to or loosely associated with sediment and other submerged surfaces (Page and Siemensma, 1991).

Flagellated Protozoa

There is a little consensus on how to classify the flagellates, and they are here divided into broad functional groups (Fig. 2). Heterotrophic flagellates are ecologically very important because they are abundant (there are seldom less than 1000 ml^{-1} , even in the plankton) and because their grazing activities are largely responsible for controlling the abundance of bacteria in aquatic environments. In some taxonomic groups, all species are exclusively heterotrophic (e.g., choanoflagellates and bodonids); others contain many mixotrophs (e.g., the euglenids and chrysomonads), whereas the haptomonads and cryptomonads are dominated by phototrophs and only a minority are capable of phagotrophy. In the past 30 years, a large diversity of heterotrophic flagellates has been discovered. Most of these are choanoflagellates, chrysomonads, euglenids, or bodonids. Some of the more easily recognized species (e.g., *Rhynchomonas nasuta*) have been recorded from a wide range of habitat types in marine, freshwater, and terrestrial environments (Patterson and Larsen, 1991; Lee and Patterson, 1998).

Many heterotrophic flagellates are anaerobes, including intestinal parasites of man (e.g., *Giardia intestinalis*), but free-living diplomonads (*Hexamita* and *Trepomonas*) and *Retortamonas* are relatively common bacteria feeders in organically enriched anoxic

Fig. 2 A selection from the variety of form and function in flagellated protozoa. (1) A choanoflagellate with bacterial food trapped on the external surface of the collar filter (*Monosiga*; body+collar $\sim 0.015 \text{ mm}$); (2) a bacteria-feeding helioflagellate (*Pteridomonas*; body 0.007 mm); (3) a phagotrophic euglenid (*Dinema*; $\sim 0.03 \text{ mm}$) with an ingested diatom; (4) a marine heterotrophic dinoflagellate (*Protoperidinium*; $\sim 0.06 \text{ mm}$) with a diatom trapped in its feeding veil; (5) a free-living, bacteria-feeding, anaerobic diplomonad (*Hexamita*; body $\sim 0.008 \text{ mm}$); (6) a small heterotrophic (bacteria-feeding) cryptomonad flagellate (*Goniomonas*; $\sim 0.008 \text{ mm}$); (7) a heterotrophic, typically bacteria-feeding, chrysomonad flagellate (*Spumella*; body $\sim 0.008 \text{ mm}$); (8) a bacteria-feeding bodonid (*Rhynchomonas*; body $\sim 0.005 \text{ mm}$).

waters and sediments. Some anaerobic flagellates have hydrogenosomes, the anaerobic derivatives of mitochondria. Almost all of these are endosymbionts or internal parasites of animals. They are also known as parabasalia and include many of medical or economic importance, e.g., the human parasite *Trichomonas vaginalis* and *Trichomitopsis*, which degrades cellulose in the hindgut of termites and other wood-eating insects and also supports endosymbiotic methane-producing bacteria (termites may be responsible for a globally significant flux of methane to the atmosphere) (Fenchel and Finlay, 1995).

Most choanoflagellates are small ($<10\ \mu\text{m}$), with a feeding filter that forms a collar around the single anterior flagellum. The flagellum creates the water current that flows through the filter. Choanoflagellates are exclusively phagotrophic and either solitary (e.g., *Monosiga*) or colonial (e.g., *Sphaeroeca*). They are important grazers of the smallest suspended bacteria, especially in the marine plankton (e.g., *Salpingoeca*, *Stephanoea*, and *Parvicorbicula*).

Euglenids usually have two flagella which emerge from a small anterior pocket. This is a large group of planktonic and benthic protozoa, common in both fresh and marine waters. Species associated with surfaces typically keep one trailing flagellum in contact with the substrate, whereas the other pulls the cell forward. Many species are green and phototrophic (e.g., *Euglena*), but there is a great diversity of phagotrophs (e.g., *Astasia*, *Petalomonas*, *Entosiphon*, and *Notosolenus*). These are especially common in marine shallow-water sediments, in which they graze on bacteria. All bodonids are small flagellates with characteristic heterodynamic flagella (e.g., *Bodo* and *Rhynchomonas*). They are almost always found in organically polluted (even anoxic) waters or soils that are rich in bacteria, on which they feed. Many closely related ("kinetoplastid") flagellates are parasites: *Ichthyobodo* causes costiasis in freshwater fish and the "trypanosomatids" are important parasites of man (*Trypanosoma brucei* causes sleeping sickness). In heterokont flagellates, each organism has two flagella – one hairy and one smooth, with the former creating the water current that brings mainly bacterial food to the (filter-feeding) flagellate. They include the bicosecids that live in a lorica (*Bicosoeca*) or are naked (*Cafeteria* and *Pseudobodo*), that may be stalked or colonial, and which resemble the mixotrophic loricate chrysomonads (e.g., *Dinobryon*).

In the phagotrophic chrysomonads (e.g., *Paraphysomonas* and *Spumella*), the chloroplast is essentially vestigial (and the cell is colorless). Functional types range from heterotrophs (e.g., *Paraphysomonas*) to mixotrophs (e.g., *Dinobryon* and *Uroglena*) and those that are predominantly phototrophs (e.g., *Symura* and *Mallomonas*). Chrysomonads are the most abundant heterotrophic flagellates in the freshwater plankton. The helioflagellates (also referred to as "pedinellid stramenopiles," e.g., *Actinomonas*, *Pteridomonas*, and *Ciliophrys*) are filter or diffusion feeders that superficially resemble heliozoa or choanoflagellates.

The haptomonads are typically photosynthetic, biflagellated organisms. They include the coccolithophorids and the prymnesiophytes, and some (e.g., *Emiliania*) are often abundant in the marine euphotic zone. They have an additional flagellar appendage known as the haptonema. In the marine *Chrysochromulina*, this is used in food uptake, but in *Prymnesium*, which has a very short haptonema, ingestion of food (dinoflagellates, chrysomonads, and green algae) is by means of a posterior pseudopodium. Prey organisms may be immobilized by toxins prior to ingestion (toxic bloom-forming species of *Prymnesium* are responsible for fish kills). The scale and importance of phagotrophy in freshwater haptomonads is unclear.

Most cryptomonads are yellow-brown and phototrophic, with two flagella of similar length (e.g., *Cryptomonas*). They are especially common in fresh waters. Heterotrophic species either lack plastids (*Goniomonas*) or have a plastid that is devoid of photosynthetic pigments (*Chilomonas*). Colorless species can be relatively abundant, especially when associated with benthic detritus.

The heteromitids and cyathobodonids represent a varied assemblage of small, poorly studied flagellates (e.g., *Apusomonas*, *Heteromita*, *Cercomonas*, *Cyathobodo*, and *Kathablepharis*), some of which (e.g., *Cercomonas*) produce pseudopodia to ingest bacteria. Others secrete a stalk (*Cyathobodo*) to attach the cell to the substrate. Many are common in soil. Others feed mainly on bacteria in the freshwater plankton (e.g., *Kathablepharis*, which also feeds on small algae) and on sediment surfaces. The percolozoans are a diverse collection of bacteria-feeding organisms, including ameboflagellates (e.g., *Naegleria*), the filter-feeding flagellate *Percolomonas*, and anaerobic flagellates with hydrogenosomes and endosymbiotic methanogens (*Psalteriomonas*).

Dinoflagellates are best known as a large group of photosynthetic flagellates and for the ability of some species to cause "toxic blooms" and "red tides" (*Protogonyaulax* causes paralytic shellfish poisoning). However, about half of all known marine species lack chloroplasts. Some of these (in the genera *Gymnodinium* and *Amphidinium*) feed on cryptomonads and sequester their chloroplasts, thus transforming themselves into mixotrophs. Moreover, many typically photosynthetic species can become mixotrophs through their ability to ingest particulate food. The nonphotosynthetic and mixotrophic species are referred to collectively as heterotrophic dinoflagellates. These can be quantitatively important in marine food webs, especially as consumers of diatoms. Some species are benthic, but little is known about these. The diversity of heterotrophic species in fresh waters is much less, and it is known mainly from the genera *Katodinium*, *Peridinium*, *Gymnodinium*, and *Ceratium*. This may be due in part to the relative rarity in fresh waters of large, chain-forming diatoms – a typical food item of many marine dinoflagellates. These large food items are trapped and digested externally in a pseudopodial feeding veil or pallium. This explains why it has often been difficult to recognize ingested organisms within dinoflagellates. Other heterotrophic dinoflagellates use a feeding tube known as a peduncle. The common freshwater dinoflagellate *Peridiniopsis berlinensis* uses such a tube to ingest the fluid contents from injured and dying protists and small metazoans.

The number of marine dinoflagellate species with a recorded capacity for phagotrophy is increasing rapidly. These include thecate species (e.g., the peridinoids) previously considered to be incapable of phagotrophy. It is widely believed that most dinoflagellates – at least in marine environments – may be capable of phagotrophy. Heterotrophic dinoflagellates (e.g., *Oblea*, *Polykrikos*, *Heterocapsa*, and *Protoperidinium*) can dominate the protozoan biomass in coastal and oceanic waters, in which they feed

on bacteria, flagellates, diatoms, other dinoflagellates, and ciliates. Their biomass can be approximately the same as that of ciliates, and the two groups may compete with each other for food (although the size range of dinoflagellates is slightly greater – from 3 or 4 μm in *Gymnodinium simplex* to 2 mm in *Noctiluca*, with the majority in the size range 20–200 μm). Also, most planktonic ciliates are incapable of ingesting the large diatoms that are consumed by dinoflagellates.

Almost all stony and stinging corals (Cnidaria) in shallow tropical waters harbor photosynthetic dinoflagellates (especially *Symbiodinium*) as symbionts. These consume carbon dioxide and bicarbonate. This promotes calcium deposition in the external skeletons of their hosts and may enhance the rate with which coral reefs are built. In the marine plankton, outbursts of parasitic dinoflagellates are sometimes associated with the collapse of zooplankton populations. The parasite *Ichthyodinium chabaudi* destroys the eggs of sardines, *Blastodinium* sp. in the copepod gut castrates its host, and *Gonyaulax catenella* (a dinoflagellate that can cause red tides) is parasitized by another dinoflagellate (*Amoebophrya ceratii*). The fossil record of dinoflagellate cysts extends over the past 220 million years, and they have a role as biostratigraphic tools.

Dinoflagellates in the marine plankton exhibit latitudinal cosmopolitanism, such that a morphospecies occurs in a circumglobal belt within fairly broad latitudinal limits which correspond to a specific temperature range in the surface waters. The recorded species richness is greatest in tropical marine waters.

Fig. 3 A selection from the variety of form and function in ciliated protozoa. (1) A bacteria-feeding tetrahymenid (*Tetrahymena*; length ~ 0.05 mm); (2) a small scuticociliate (*Cyclidium*; length ~ 0.02 mm) filter feeding on bacteria; (3) a bacteria-feeding colpodid ciliate (*Colpoda*; length ~ 0.02 mm) from soil; (4) an anaerobic, typically benthic plagiopylid feeding on bacteria (*Plagiopyla*; length ~ 0.1 mm); (5) a large haptorid (*Dileptus*; length ~ 0.4 mm) with toxicysts used to kill motile prey (flagellates and other ciliates) prior to ingestion; (6) a planktonic, loricated, diatom-feeding tintinnid (*Tintinnopsis*; length ~ 0.1 mm); (7) a gymnostome ciliate (*Coleps*; length ~ 0.07 mm) about to ingest a dinoflagellate; (8) a diatom-feeding karyorelictid (*Remanella*; length ~ 0.12 mm) typical of the marine interstitial; (9) a “hoover-feeding” cyrtophorid (*Chilodonella*; length ~ 0.04 mm) ingesting a diatom; (10) a planktonic oligotrich (*Halteria*; diameter ~ 0.04 mm) filter feeding on small algae; (11) a “diffusion-feeding” suctorian (*Podophrya*; diameter ~ 0.04 mm) with a flagellate trapped on a feeding tentacle.

Ciliated Protozoa

This diverse and distinctive group uses cilia for locomotion and feeding (Fig. 3). They demonstrate a considerable adaptive radiation of feeding mechanisms and cell morphologies (e.g., the ribbon-shaped forms *Tracheloraphis* and *Geleia* adapted for life in the marine interstitial) (Fenchel, 1987; Lynn, 2008). The smallest species tend to feed on bacteria-sized particles and the larger species on unicellular algae, filamentous cyanobacteria, other protozoa, and even rotifers and other microzooplankton. The raptorial feeders (e.g., *Prorodon*) use a simple mouth to catch diatoms, dinoflagellates, and other large food items individually; some (e.g., *Lacrymaria*) kill motile prey, whereas others (e.g., *Chilodonella*) “hoover” diatoms and other elongate food particles from surfaces. The filter feeders (e.g., *Cyclidium*) use fine-mesh filters to sieve suspended bacteria, and some of these ciliates (e.g., *Paramecium* and *Tetrahymena*) thrive in habitats with very high bacterial concentrations. Other ciliates (e.g., *Pleuronema* and *Tintinnopsis*) use coarser filters to collect small algae. In many ciliates (e.g., *Oxytricha*, *Aspidisca*, and *Strombidium*), a row of membranelles generates a water current and acts as a relatively coarse feeding filter, and some of these ciliates (e.g., *Euplotes*) feed most efficiently if they are raised on cirri (fused cilia). Many ciliates are typically sessile and aligned perpendicular to the substrate (e.g., *Stentor* and *Vorticella*). Diffusion feeders (e.g., *Podophrya* and other Suctorina) catch swimming prey (usually other protozoa) that collide with their sticky tentacles.

More is probably known about the biodiversity and ecology of free-living ciliates than any other protozoan group. There are several reasons for this, including the distinctive and immediately recognizable ciliate morphology and swimming behavior and the relative ease with which many species can be cultured. They are a group of predominantly free-living protozoa. A few are parasites (e.g., *Ichthyophthirius* infects fish and there is one human endoparasite of minor importance – *Balantidium coli*), but most species are either free-living or harmless commensals of aquatic invertebrates (the ciliate epifauna of marine crustaceans is particularly diverse). Free-living species are known from all natural aquatic habitats in which temperatures are $<45^{\circ}\text{C}$, including oceanic sinking detritus, freshwater and marine sediments, anaerobic municipal landfill sites, and sewage treatment plants. They are abundant (up to $\sim 106\text{ ml}^{-1}$) in activated sludge plants, in which they consume bacteria and also flocculate bacteria and other suspended particulate matter. These activities aid the clarification of the effluent and the formation of sludge. About a dozen ciliate species are frequently recorded in used-water treatment plants, although more than 200 ciliate species have been recorded. Ciliates also have a role as indicators of the level of organic pollution in river water (Corliss, 1979, 2000; Lynn, 2008).

Most ciliates are in the size range 0.02–2 mm, so they are generally larger than the heterotrophic flagellates and other nanoplankton (0.002–0.02 mm) on which many of them feed. Planktonic ciliates are relatively abundant ($1\text{--}100\text{ ml}^{-1}$) and important grazers of nanoplankton in marine and fresh waters. They are probably key grazers within the microbial loop which is responsible for the rapid remineralization of organic matter in the water column. The diet of planktonic metazoans includes ciliates, although the quantitative significance of this link is unclear. Benthic ciliates are often abundant ($>1000\text{ ml}^{-1}$) and usually the most important grazers in freshwater sediments (especially in lakes) and marine sandy sediments of inshore waters.

Many ciliate species harbor prokaryotic or eukaryotic symbionts. At the oxic–anoxic boundary in the water column of lakes, most ciliates may harbor sufficient endosymbiotic algae (*Chlorella*) to render the consortia capable of net photosynthesis in dim light. The marine interstitial ciliate *Kentrophoros* carries ectosymbiotic chemolithotrophic sulfide-oxidizing bacteria, and most anaerobic ciliate species harbor methanogenic bacteria that act as a sink for (potentially inhibitory) H_2 produced by the ciliate. The endosymbiotic nonsulfur purple bacteria in the anaerobic ciliate *Strombidium purpureum* use waste H_2 from the ciliate as a reductant for photosynthesis. Most marine anaerobic ciliates carry ectosymbiotic sulfate-reducing bacteria (Fenchel and Finlay, 1995).

Many ciliate species are microaerobic, and they seek out the (microbe-rich) oxic–anoxic boundary in sediment or the water column. Some of these species are facultative anaerobes (in the genera *Cyclidium*, *Euplotes*, *Strombidium*, and *Paranophrys*). There are approximately 70 known species of anaerobic free-living ciliate species, mainly in the genera *Metopus*, *Caenomorpha*, *Saprodinium*, *Epilaxella*, *Trimyema*, and *Plagiopyla*. It is likely that all these contain hydrogenosomes.

Anaerobic ciliates also live as endocommensals in the enlarged forestomach (rumen) of ruminants and in the cecum of other mammals with postgastric fermentation. It is unlikely that any of these ciliates (e.g., in the genera *Dasytricha*, *Entodinium*, and *Polypylaston*) are capable of a free-living existence. Rumen ciliates are typically extremely abundant ($105\text{--}106\text{ ml}^{-1}$ of rumen liquor). They consume bacteria and microscopic fragments of grass and other plant material. Some species are capable of degrading cellulose and other structural carbohydrates, and the endosymbiotic methanogenic bacteria in some species contribute to the methane emitted from the ruminants. The economic significance of such large numbers of ciliates living in the rumen is unclear.

Ciliates also live in soil, in which all species are probably capable of producing desiccation-resistant cysts (e.g., *Colpoda*). The abundance of active ciliates in soil is extremely variable and reflects repeated cycles of cyst formation and excystment in response to fluctuating physical factors such as the level of soil moisture. Many species found in soil are frequently found in other (predominantly freshwater) habitats, although only about 200 ciliate species have been described from soil.

Others

The following are often referred to as protozoa. Because they are endocommensals or parasites, or incapable of phagotrophy, they do not fall within the definition of protozoa used here (i.e., free-living unicellular phagotrophs). They are mentioned briefly for the sake of completeness but are excluded from Table 1.

Chytridiomycetes, oomycetes, and hyphochytridiomycetes have the typical fungal characteristics of saprotrophic (absorptive) nutrition and cell walls in the vegetative state. Some are economically important (the oomycete *Phytophthora infestans* causes potato

blight). The plasmodiophorids are cell wall-free endoparasitic slime molds (*Plasmodiophora brassicae* causes club root disease in cabbages). The labyrinthulids (e.g., the “slime net” *Labyrinthula*) feed saprotrophically, especially on marine algae, and form complex branching colonies of spindle-shape cells that move through slime channels. All five groups reproduce by means of unicellular flagellated zoospores (hence, they are also known as “zoosporic fungi”).

The opalinids superficially resemble ciliates, but all are mouthless endocommensals living in the hindgut of amphibians and some fish (Lee et al., 2000). The microsporidians are a large group (~800 species) of intracellular parasites of animals and other protozoa. They extrude a tubular filament through which the spore is injected into the host cytoplasm. They are believed to be highly derived fungi rather than early diverging eukaryotes. The haplosporidians are a small group of parasites of aquatic invertebrates, notably marine mollusks, and the parabasalans (anaerobic flagellates with hydrogenosomes, e.g., *Trichomonas*) are all parasites, with one or two possible exceptions (*Pseudotrichomonas*).

The organisms now referred to as apicomplexans used to be an important component of the sporozoans. All are intracellular parasites of animals, and many cause life-threatening diseases of man. They share the distinctive morphological feature of an apical complex at certain stages in the polymorphic life cycle. The degree of host specificity of many apicomplexans is not known. They include the gregarines that infect insects, marine polychaetes, and other invertebrates (e.g., *Monocystis* in earthworms), and also the “coccidian” parasites including *Toxoplasma gondii* (the domestic cat is the final host, but intermediate infection in the human can cross the placenta) and about 1050 species of *Eimeria* infecting mammals, chickens, and other farmed birds. *Cryptosporidium* is an apicomplexan, and eight species are known that infect the digestive and respiratory systems of vertebrates. *Cryptosporidium parvum* infects humans and cattle, and waterborne transmission of oocysts is thought to complete the fecal–oral cycle. Infection can cause life-threatening diarrhea in immunocompromised humans. *Cryptosporidium* may be sufficiently different from other coccidians to warrant creation of the new higher taxon “cryptosporidia.” *Plasmodium*, the causative agent of malaria, is an apicomplexan, as is *Pneumocystis*, which is an enigmatic parasite that can persist in the human lung for long periods. *Pneumocystis carinii* (currently renamed as *Pneumocystis jirovecii*) causes *Pneumocystis* pneumonia in HIV patients. In the early 1970s, the organism was considered to be a fungus; in the early 1980s it was considered to be an apicomplexan, and by the late 1980s it was again considered to be a fungus, possibly an ascomycete. Confusingly, it can resemble *Cryptosporidium* when viewed with the light microscope. There are approximately 4000 nominal species of apicomplexans.

The Myxozoans are a large group (~1200 species) of parasites, of which the myxosporidians are important parasites of farmed fish (*Myxobolus cerebralis* causes “torsion disease” in trout). During their life cycle they show both protozoan and metazoan characters. Recent gene sequence data (1818S rDNA rDNA) indicate that myxozoans are grossly modified and simplified metazoans of the phylum Cnidaria (Siddall et al., 1995; Okabmura et al., 2015).

Glossary

Cleaved complexes Quinolone-topoisomerase-DNA complexes that contain broken DNA covalently attached to a topoisomerase.

DNA gyrase The enzyme responsible for introducing negative supercoils into DNA. The genes encoding gyrase are *gyrA* and *gyrB*.

DNA topoisomerase IV The enzyme responsible for decatenating (separating) interlinked circles of DNA at the end of a round of replication; also relaxes DNA. The genes encoding topoisomerase IV are *parC* and *parE*.

Minimal inhibitory concentration (MIC) The lowest concentration of an antimicrobial that blocks the growth of a given bacterial strain or isolate, generally when 10^4 to 10^5 bacteria are tested.

Mutant prevention concentration (MPC) The concentration of an antimicrobial that blocks the growth of the least susceptible resistant mutant subpopulation within a large bacterial population; approximated at no colony recovered when 10^{10} bacteria are applied to drug-containing agar plates.

Reactive oxygen species (ROS) Toxic molecules, such as superoxide, hydrogen peroxide, and hydroxyl radical, that participate in bacterial self-destruction following treatment with lethal concentrations of quinolones.

Introduction

The quinolone antibacterials have evolved into a diverse group of compounds that target two essential bacterial enzymes, DNA gyrase and DNA topoisomerase IV. While most of the compounds are true quinolones, the group also includes naphthyridines (nalidixic acid, gemifloxacin) and quinazolinodiones. Quinolone development was initially driven by the need to broaden the spectrum of susceptible pathogens, since the prototype compound, nalidixic acid, is active only with a few Gram-negative bacteria. Its replacement, norfloxacin, is still used clinically due to good activity and pharmacokinetic properties. Ciprofloxacin succeeded norfloxacin by substitution of a cyclopropyl group at the N-1 position, which improved both lethal activity and the number of susceptible species. Indeed, ciprofloxacin remains the most effective quinolone with Gram-negative bacteria; however, activity with Gram-positive organisms is marginal. Adding a halogen or methoxy moiety to position C-8 and a variety of changes in the C-7 ring system improved Gram-positive activity. Compounds with these changes are sparfloxacin, moxifloxacin, and gatifloxacin. Other important compounds, such as levofloxacin and gemifloxacin, developed along different pathways. Keeping track of the various quinolone groupings can be important, since they have different mechanistic properties.

As quinolone activity improved, use of the compounds increased markedly, and resistance developed. Resistance recently entered a new phase with the emergence of plasmid-mediated resistance. The present challenge is to find ways to overcome resistance, an effort that likely involves understanding how quinolones poison bacterial cells. It may also involve changing the focus of antimicrobial therapy from curing disease to restricting resistance, a change that would require using higher doses. The present article seeks to provide an understanding of quinolone action and resistance as a way toward preserving the utility of the compounds.

Understanding quinolone action focuses on topoisomerase mechanism. The two enzyme targets of the quinolones, DNA gyrase and DNA topoisomerase IV, act by passing one region of duplex DNA through another using a strand cleavage-rejoining

[☆]*Change History:* August 2014. X Zhao, M Malik, Y Hong, L Li, and K Drlica, have made changes in Quinolone mechanism and resistance is an active area of research; consequently, the previous version of this article was completely rewritten. New results include the involvement of reactive oxygen species in quinolone-mediated cell death, the discovery of a second quinolone-binding mode in cleaved complexes, and the finding that quinolone resistance is due largely to loss of a drug-magnesium-enzyme bridge when mutations occur in GyrA or ParC. The mutant selection window hypothesis continues to serve as a framework for describing the selective enrichment of resistant mutants, and quinolone dosing continues to place drug concentrations inside the selection window.

This article is an update of K. Drlica, X. Zhao, M. Malik, Quinolones, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 707–716.

mechanism. During that process the drugs trap a reaction intermediate as a drug–enzyme–DNA complex. The resulting complexes block DNA replication rapidly (within minutes) and inhibit bacterial growth. At elevated drug concentrations, cell death can be observed within 30 min to an hour, depending on the quinolone and bacterial species. Resistance results from a variety of factors that include reduction of intracellular drug concentration and binding to the target proteins. The genetic changes underlying resistance arise in three general ways: through spontaneous mutation, through the mutagenic SOS response, and through plasmid-mediated mobilization of protective chromosomal genes. Resistant bacterial subpopulations are then selectively enriched by suboptimal quinolone treatment, and the resulting resistant clones disseminate. We begin by describing the drug–enzyme complexes that form on DNA.

Cleaved Complexes

As a part of their reaction mechanism, gyrase and topoisomerase IV introduce a pair of staggered, single-strand breaks into DNA and become covalently linked to the 5' ends of the broken DNA. Quinolones bind to the enzyme–DNA complexes, probably before DNA cleavage occurs, and by intercalating into DNA they prevent the enzymes from religating the broken DNA ends. The resulting ternary complexes, called cleaved complexes due to the presence of DNA breaks, block the movement of DNA and RNA polymerases. Treatment of cleaved complexes with protein denaturants, such as sodium dodecyl sulfate (SDS), releases the DNA ends from protein-mediated constraint, and broken DNA is readily observed. Since the topoisomerases have access to most regions of the chromosome, quinolone treatment creates DNA break-containing complexes throughout the chromosome.

An important feature of complex formation is reversibility, which can be observed as resealing of broken DNA following removal of quinolone, mild thermal treatment, or addition of the chelating agent EDTA. Chromosome supercoiling is not relaxed by quinolone treatment. Thus, the ends of the broken DNA must be constrained in the complexes. That constraint, which facilitates DNA resealing, prevents massive DNA relaxation when DNA exits from the protein at the conclusion of the strand passage reaction.

The reversible nature of complex formation emphasizes that cleaved complexes are not by themselves lethal. Indeed, complex formation correlates with bacteriostatic activity, commonly measured as minimal inhibitory concentration or efficiency of plating. In both of these assays the quinolone is present in the medium used to score growth. We emphasize this point, because such assays are sometimes mistakenly thought to reflect killing of cells. To measure lethal action, the cells are challenged with drug and then plated under non-selective conditions. Since separation of challenge and colony scoring is generally not performed with genetic procedures such as transduction, the term 'conditional-lethal mutant' is often a misnomer.

Cleaved complexes have been crystallized, and their structures have been analyzed by X-ray crystallography. Consequently, we now know that a pair of quinolone molecules intercalate into broken DNA such that the C-7 ring system faces the GyrB/ParE subunits. The carboxyl end of the compounds extend to helix-4 of GyrA/ParC (gyrase is composed of two subunit types, GyrA and GyrB, which in topoisomerase IV are called ParC and ParE). The amino acid substitutions most often associated with clinical resistance are located in helix-4. Resistance is explained by changes in amino acids at positions 83 and 87 (*Escherichia coli* GyrA numbering system) that disrupt a magnesium–water bridge formed between the quinolone C-3-carboxyl, C-4-keto, and gyrase or topoisomerase IV. Disruption destabilizes drug binding. Quinazolinodiones, which lack the 3-carboxyl group, cannot form the magnesium bridge, and their activity is unaffected by substitutions at positions 83 and 87. Unfortunately, the diones are less active than their cognate quinolones; consequently diones do not yet substitute for fluoroquinolones. Current work aims to find new ways to stabilize cleaved complexes formed with diones and to reduce crossover activity of diones with human topoisomerase II.

A second drug–enzyme interaction has been identified by crosslinking between the C-7 ring of quinolones to GyrA-81, which is far from the GyrB interaction site seen in the crystal structures. This second interaction can be explained in two ways that have not been distinguished. One involves an inversion of drug binding orientation shown in the crystal structure such that the C-7 ring system extends to helix-4 of GyrA/ParC. A second postulates the existence of an additional drug-binding site. Examination of the surface of GyrA/ParC reveals a potential binding pocket that bridges the interface between the GyrA (ParC) subunits. This second binding site is potentially important, because it might allow additional drug molecules to bind to the complexes and help explain why rapid killing requires higher drug concentrations than inhibition of growth.

Chromosome Fragmentation, ROS, and Cell Death

Since even a few chromosomal DNA breaks can be lethal and since quinolone–topoisomerase complexes that contain broken DNA are distributed throughout the *E. coli* chromosome, we considered the possibility that lethal chromosome fragmentation arises from the release of DNA breaks constrained in the complexes. Constraint was initially observed as maintenance of DNA supercoils in nucleoids extracted from cells treated with concentrations of quinolone that block DNA synthesis and trap broken DNA in ternary complexes. When quinolone concentrations were increased to levels that rapidly kill cells, nucleoids lost the ability to maintain supercoils, even in the presence of ethidium bromide, an intercalating dye that would otherwise introduce supercoils. Since supercoiling in nucleoids is partitioned into many topologically independent domains, the inability to maintain supercoiling is

most readily explained by widespread chromosome fragmentation. When inhibition of protein synthesis blocks quinolone-mediated lethality, it also blocks quinolone-mediated loss of supercoiling. Thus, supercoiling assays provide a correlation between chromosome fragmentation and cell death.

Chromosome fragmentation has also been measured more directly. One method involves treating *E. coli* with quinolone and then measuring cell lysate viscosity. Cell lysates, when prepared by gentle methods, can exhibit little viscosity; subsequent heating unfolds the nucleoids and causes lysates to become very viscous. If chromosomes are fragmented by quinolone action, lysates fail to become viscous when heated. Another assay involves sedimentation of DNA into sucrose density-gradients: broken DNA sediments slowly.

Both viscosity and sedimentation measurements indicate that nalidixic acid causes chromosome fragmentation having kinetics similar to cell death and much slower than inhibition of DNA replication. Additional correlations are revealed by inhibition of protein synthesis, which blocks both killing by nalidixic acid and chromosome fragmentation. However, inhibitors of protein synthesis do not interfere with cleaved complex formation because cells co-treated with chloramphenicol and nalidixic acid still reveal DNA breaks upon treatment with sodium dodecyl sulfate (SDS). Therefore, complex formation and cell death are distinct processes in which cell death correlates with chromosome fragmentation.

How nalidixic and oxolinic acids cause chromosome fragmentation is not known. The inhibition of nalidixic acid-mediated cell death by chloramphenicol, an inhibitor of protein synthesis, suggests that a suicide factor is involved. Such a factor is likely to be short-lived, since the lethal action of nalidixic acid is rapidly blocked by addition of chloramphenicol even after killing by quinolone has progressed for 45 min.

Surprisingly, cell death due to treatment with nalidixic and oxolinic acids does not arise directly from chromosome fragmentation. Instead, the fragmentation, which we postulate is the initial lesion, stimulates a cascade of reactive oxygen species (ROS; commonly studied species are superoxide, hydrogen peroxide, and hydroxyl radical). That explains why the lethal effect of quinolones is increased by a deficiency in KatG, an enzyme that converts hydrogen peroxide to water. Moreover, quinolone lethality is blocked by agents expected to reduce the accumulation of hydroxyl radical (a highly toxic ROS) and by passing an anaerobic gas mixture through *E. coli* cultures.

Not all quinolones behave like nalidixic and oxolinic acids. For example, cell death caused by norfloxacin is also blocked by chloramphenicol, but at high concentration norfloxacin kills cells during anaerobic growth (low, but aerobically lethal concentrations do not kill anaerobically). Norfloxacin also kills cells resuspended in saline, while nalidixic acid does not. Thus norfloxacin action and nalidixic acid action are distinct. More potent quinolones, such as ciprofloxacin and gatifloxacin, fragment chromosomes and kill cells in the presence of protein synthesis inhibitors. Some compounds, such as PD161144 (a C-8 methoxy experimental fluoroquinolone), do not require ROS to kill cells, and in some bacterial species ROS accelerate cell death rather than increase the fraction of cells killed. To explain these diverse effects of quinolone structure, we postulate the existence of two pathways by which quinolones kill cells. Some compounds kill by both pathways, with the relative contribution of each pathway dependent on drug structure and concentration. In the next section we speculate about quinolones-mediated killing in the absence of protein synthesis.

Before proceeding, we note that several challenges to involvement of ROS in quinolone-mediated lethality have led to refinements that firmly establish the phenomenon. The challenges are instructive because they reveal the complexity of the phenomenon and the importance of focusing assays sharply on the lethal response to quinolone treatment (factors acting before lesion formation, such as drug uptake and efflux, are largely irrelevant to the response).

Cleaved Complex Destabilization and Cell Death

Although incubation of reaction mixtures containing plasmid DNA, gyrase, and quinolone has never revealed DNA breaks without addition of SDS, we have seen chromosome fragmentation when nucleoids are used as substrates for complexes formed with purified gyrase and gatifloxacin, a very active fluoroquinolone. Nalidixic acid failed to exhibit this behavior unless the gyrase in the reaction was a mutant form that allows the drug to kill *E. coli* in the presence of chloramphenicol. This GyrA variant contained an amino acid substitution that was expected to weaken the GyrA-GyrA interaction at the interface of the two subunits in gyrase. Since a weakened dimer interaction could promote gyrase subunit dissociation and release of DNA breaks, we speculated that chromosome fragmentation can derive from cleaved complex destabilization. It is not known why cleaved complex destabilization is not observed with plasmid DNA as a substrate.

Several other observations also fit with the cleaved complex destabilization hypothesis. One emerged from studies of quinolone-stimulated illegitimate recombination, a phenomenon most easily explained by gyrase subunit dissociation-reassociation. A second concerns a GyrB mutation that allows oxolinic acid to kill *E. coli* in the presence of chloramphenicol. Other observations distinguish the two lethal pathways. For example, the complex destabilization pathway is sensitive to the *lexA-3* mutation, while the ROS pathway is not. In another example, fluoroquinolone PD161144 kills *E. coli* in the presence of chloramphenicol, agents that interfere with hydroxyl radical accumulation, and during anaerobic growth, none of which occur with oxolinic acid. Thus, there is little doubt that a distinct pathway occurs, but the underlying mechanism is far from established.

The connection between cleaved complex destabilization and chloramphenicol-insensitive killing allows conclusions to be drawn about effects of quinolone structure. For example, the N-1 cyclopropyl group appears to be important for complex

destabilization, since this group is the only difference between ciprofloxacin, a compound that kills in the presence of chloramphenicol, and norfloxacin, a compound that does not. The C-8-methoxy group is also important, since it increases chloramphenicol-insensitive killing by fluoroquinolones. A third factor is the structure of the C-7 moiety. With mycobacteria, the large C-7 ring system of moxifloxacin increases chloramphenicol-insensitive lethality relative to that of gatifloxacin, another C-8-methoxy compound with a small C-7 ring. With *E. coli*, the C-7 N-ethyl piperazine of PD161144 confers maximal activity. This effect of quinolone structure on ternary complex destabilization can be explained if the N-1 cyclopropyl and C-8 methoxy groups enhance binding to helix-4 while the C-7 rings, pointing across the GyrA-GyrA dimer interface, destabilize the dimer interaction. The subunit bridging model derived from C-7 ring-GyrA-81 crosslinking (see last paragraph of section 'Cleaved Complexes') could allow such an interaction.

Genes Involved in Fluoroquinolone Resistance

Clinical fluoroquinolone resistance arises in a step-wise fashion in which each mutation increases the probability that a given strain will acquire another mutation. The gradual hill-climb to resistance can begin with mutations that only moderately lower susceptibility or with high-level target mutations that can confer resistance in a single step. Continued quinolone exposure selects additional mutations. Below we briefly describe the major types of resistance.

Permeability-Based Resistance

Gram-negative bacteria have two cell envelope membranes. In enterobacteria, the outer membrane is composed of two layers, an outer surface of lipopolysaccharide and an inner phospholipid bilayer. Underlying the phospholipid is a peptidoglycan network. Proteins called porins serve as channels for certain hydrophilic molecules; decreased quinolone susceptibility can correlate with a deficiency in particular porin protein. The highly charged lipopolysaccharide probably serves as a permeability barrier to hydrophobic quinolones, since alterations in that layer can also affect quinolone susceptibility.

In *E. coli*, membrane-associated quinolone resistance sometimes arises following selection for resistance to chloramphenicol or tetracycline. This phenomenon is explained in part by the multiple antibiotic resistance (Mar) system affecting expression of the OmpF (outer membrane protein F) porin. Mutation of *marA* increases expression of *micF*, a gene encoding an RNA that post-transcriptionally decreases *ompF* mRNA. Therefore, upregulation of MarA reduces the amount of OmpF and thereby uptake of quinolone. The influence of *marA* on quinolone uptake is not restricted to OmpF, since susceptibility of *marA* mutants is lower than when *ompF* is simply deleted and since deletion of *micF* in a *marA* mutant fails to restore wild-type susceptibility. Thus a complex regulatory network probably governs entry of particular compounds into the cell.

Efflux-Based Fluoroquinolone Resistance

Fluoroquinolone resistance due to efflux generally arises from up-regulation of genes involved in removal of toxic agents from cells. Gram-negative bacteria contain two types of efflux system. One type is composed of at least three proteins, a transporter located in the cytoplasmic membrane, an outer membrane channel, and a periplasmic linker. The transporter proteins fall into two general groups. One is called the major facilitator superfamily (MFS), which is characterized by 12–14 transmembrane helices and uses proton motive force for energy. MFS members export nalidixic acid. The other family is called RND (resistance-nodulation-cell-division) superfamily. Proteins in this group contain 12 transmembrane helices plus two large periplasmic domains that are absent in the MF family. RND systems also use proton motive force to export fluoroquinolones and other antimicrobial agents.

The *E. coli* genome has 29 potential efflux pumps, nine of which are known to export drugs when expressed at high level. The AcrAB-TolC system is among the better characterized. This three-component system crosses both the inner and outer membranes. The inner membrane protein, AcrB, is a transporter of the RND type. It exports many agents including fluoroquinolones, tetracycline, β -lactams, chloramphenicol, erythromycin, rifampicin, disinfectants, dyes, and organic solvents. The TolC protein, which is anchored in the outer membrane, forms a long channel that spans both the outer membrane and the periplasmic space. AcrA is a lipoprotein located in the periplasm that is thought to coordinate AcrB and TolC activity. Strains deficient in the AcrAB proteins are hypersusceptible to quinolones. Conversely, fluoroquinolone-resistant efflux mutants often overproduce the periplasmic protein AcrA, which lowers the accumulation of ciprofloxacin and ethidium bromide. It also decreases susceptibility to tetracycline, ampicillin, and chloramphenicol.

Two global regulatory systems, the *marRAB* and *soxRS* systems, are involved in expression of the AcrAB-TolC system. The MarA (multiple antibiotic resistance A) and SoxS proteins are positive regulators; MarR and SoxR are repressors that down-regulate *marA* and *soxS*, respectively. Fluoroquinolone-resistance mutations sometimes map in the repressor genes and sometimes in the operators of the *mar* or *sox* operons. The two positive regulators, MarA and SoxS, also down-regulate OmpF, which, as pointed out above, is an outer membrane protein that facilitates fluoroquinolone uptake. Thus increased efflux can be coupled to decreased permeability.

Among Gram-positive bacteria, two principal efflux systems have been described, both of which fall in the MF family. One is called the Bmr (Bacillus multidrug resistance)-NorA (norfloxacin resistance) group; the other is termed the QacA (quaternary ammonium compound export) group. Some staphylococci also produce the Smr (small multidrug resistance) pump, an unusually small transporter that contains only four transmembrane helices.

The ability to efflux fluoroquinolones is associated with a propensity to acquire additional fluoroquinolone resistance determinants. In the case of an inhibitor of efflux or with efflux-deficient strains, recovery of resistant mutants decreases, sometimes by orders of magnitude. Conversely, fluoroquinolone-resistant efflux mutations are associated with an increase in the recovery of additional fluoroquinolone-resistance determinants. These effects are likely to arise from changes in intracellular drug concentration, since mutant recovery for many species depends strongly on fluoroquinolone concentration, as discussed below.

Qnr

Examination of plasmids for quinolone resistance led to the discovery of a protein family called Qnr. Qnr proteins can profoundly influence cleaved complex stability and interfere with quinolone action. When gene probes are used to screen clinical isolates for members of the Qnr family, about 8% (6/78) of *E. coli* isolates of Chinese origin are found to contain plasmid-borne *qnrA*. A similar result was later found with *E. coli* and *K. pneumoniae* isolates from the United States. These results pose a new challenge for maintaining the quinolones as effective antibacterial agents.

Target-Enzyme-Based Resistance

As pointed out in previous sections, gyrase and topoisomerase IV are the intracellular targets of the quinolones; mutations in the gyrase genes (*gyrA*, *gyrB*) and topoisomerase IV genes (*parC*, *parE*) lower susceptibility. For both *gyrA* and *parC*, resistance mutations map within a narrow stretch of nucleotides termed the quinolone-resistance-determining region (QRDR), which in *E. coli gyrA* encodes amino acids 51 through 106 (in *S. aureus*, mutations that lower susceptibility are distributed over a larger region). Resistance mutations mapping in *gyrB* and *parE* often reduce susceptibility by only moderate amounts, and they tend to be acquired after *gyrA* and *parC* alleles are fixed in the population. Most clinically resistant isolates contain a mutation in either *gyrA*, *parC*, or both. Those mutations generally alter amino acids at *E. coli* GyrA positions 83 and 87 as pointed out above.

Quinolone Concentration and Acquisition of Resistance

The quinolones are widely known as inducers of the mutagenic SOS response. The importance of this property was emphasized when an *E. coli* infection of mouse thigh was treated with quinolone: many more resistant mutants were recovered when the infecting strain was wild-type than when it carried a *lexA* mutation that prevents induction of the SOS regulon.

Quinolone concentration is expected to have two effects on the induction of resistance. First, it must be high enough to induce the SOS response. Second, it must not be too high, since cells will be killed before mutant gyrase replaces susceptible gyrase or before other quinolone-resistance mutations are fixed in the population. Thus, a threshold concentration should exist above which induced mutations are not fixed. The traditional approach for quinolone dosing has been to use MIC as a threshold (for fluoroquinolones, values of MIC are often only slightly higher than values of minimal bactericidal concentration (MBC), making it likely that drug concentrations above MIC kill susceptible cells and reduce the size of the bacterial population). To accommodate fluctuating drug concentrations during treatment, concentration is expressed by the pharmacokinetic term AUC (area under the time-concentration curve), often obtained by administering drug to human volunteers. Combining AUC with bacterial susceptibility (MIC) produces a term (AUC/MIC) that estimates drug exposure in the host. AUC/MIC is then measured and related empirically to favorable clinical outcome, which is assumed to also restrict the acquisition of resistance.

Traditional pharmacodynamic approaches for restricting mutants, popularly expressed by the phrase 'dead bugs don't mutate,' do not consider mutant subpopulations that are present prior to initiation of therapy: quinolone concentrations that kill susceptible cells do not necessarily kill mutant subpopulations and can allow those mutants to amplify if concentrations fall within a specific range called the mutant selection window. The boundaries of the range were defined experimentally by measuring the recovery of mycobacterial mutants from quinolone-containing agar. As drug concentration is increased, the number of colony-forming units recovered drops sharply, levels to a broad plateau, and then drops sharply a second time. The sharp drop at low concentration occurs when the growth of wild-type cells is inhibited. This concentration, which is approximated by MIC, defines the lower boundary of the selection window, since little selective pressure exists at drug concentrations below such a boundary. The second sharp drop defines the upper boundary of the window. The upper boundary, which is the concentration that blocks growth of the least susceptible, single-step mutant, is called the mutant prevention concentration (MPC). For growth above that concentration, susceptible bacterial cells must acquire at least two resistance mutations concurrently, an event that is expected to occur rarely.

Examination of *M. smegmatis* mutants selected inside the window reveals that low concentrations of fluoroquinolone select nongyrase mutations, of which about 60% exhibit cross-resistance to ampicillin and chloramphenicol. As fluoroquinolone concentration is increased, these variants decrease in prevalence and *gyrA* mutants increase. At high fluoroquinolone concentration, colonies arise only from the GyrA variant that has the highest MIC. Eventually the MPC is exceeded, and colony recovery occurs only very rarely. *Streptococcus pneumoniae* exhibits a similar phenomenon: non-topoisomerase mutants are obtained by challenge with low fluoroquinolone concentration, and increasing the drug concentration shifts mutant recovery to either GyrA or ParC variants,

depending on the particular fluoroquinolone being examined. Thus low doses or marginally effective derivatives are more likely than high doses or highly effective compounds to enrich pre-existing and induced mutants that can then serve as populations for induction of even higher resistance. However, maintaining drug concentration above the selection window, above MPC, should restrict the selective amplification of resistant mutant subpopulations.

Once a target (gyrase or topoisomerase IV) mutant has been enriched, a change occurs in the relationship between fluoroquinolone concentration and the recovery of additional resistance mutations. For example, with *Streptococcus pneumoniae*, the steep dependency of mutant recovery on drug concentration shifts to a broad plateau with an elevated value of MPC (the window widens). With *Haemophilus influenzae*, each successive mutation raises the selection window (the window increases its overlap with drug concentrations achievable in the patient). Both phenomena increase the ease with which additional resistance mutations can be acquired. Thus controlling resistance becomes more difficult as resistance mutations accumulate in bacterial populations.

Plasmid-Mediated Resistance

Fluoroquinolone resistance genes carried by plasmids pose a serious threat to quinolone efficacy for two reasons. First, plasmids can carry genes for resistance to multiple antibiotics, which means that fluoroquinolone resistance can be acquired through the use of other antimicrobial classes. Second, plasmids can enter a bacterial population at a much higher frequency than spontaneous resistance mutations. That makes cells carrying plasmid-mediated resistance a larger fraction of the bulk population and more likely to become the dominant class when fluoroquinolones are applied.

The best-studied family of plasmid-mediated fluoroquinolone-resistance genes is called *qnr*. Five major family groups, termed *qnrA*, *qnrB*, *qnrC*, *qnrD*, and *qnrS*, have been identified, and some family groups have many members (seven forms of *qnrA* and 42 forms of *qnrB* have been found). Thus, the *qnr* determinants are highly diverse. Surveys that revealed Qnr diversity also show that Qnr-expressing plasmids are globally distributed and that they occur in a wide variety of bacterial species. Since plasmids carrying a QnrA determinant often mediate resistance to aminoglycosides, β -lactams, chloramphenicol, and sulfonamides, Qnr is likely to be a major contributor to antimicrobial resistance in general.

A second type of plasmid-borne resistance gene expresses the quinolone-acetylating enzyme Aac (6')-Ib-cr. This factor lowers the activity of compounds, such as ciprofloxacin and norfloxacin, by about 4 fold. The geographical distribution of *aac (6')-Ib-cr* has not been studied as thoroughly as that of *qnr*. Nevertheless, it is clear that drug-modification-based resistance is widely distributed. As with *qnr*, *aac (6')-Ib-cr*-containing plasmids are found in a variety of Enterobacteriaceae, and the prevalence of *aac (6')-Ib-cr* can be substantial. Since *aac (6')-Ib-cr* is part of an integron cassette, it is likely to move readily among plasmids. Indeed, fluoroquinolone-resistance plasmids are conjugative and tend to have a broad host range.

Plasmid-mediated quinolone resistance also involves efflux pumps. The QepA efflux pump increases MIC about 10-fold for hydrophilic fluoroquinolones, such as norfloxacin and ciprofloxacin. So far, the prevalence of QepA-mediated resistance in humans is low. Another *E. coli* efflux system, *oqxAB*, has recently been found in food animals in China and Denmark, and plasmid-mediated efflux has been reported in *S. aureus*. Such reports are likely to increase now that laboratories are looking for efflux determinants.

Plasmid-mediated resistance appears to derive from mobilization of chromosomal genes followed by enrichment due to environmental contamination with quinolones. The presence of integrons in conjugative plasmids is known to mobilize other chromosomal genes; thus, a potential mechanism is available. Since some aquatic bacteria contain chromosomal genes for *qnrA* and *qnrS*, the idea has developed that gene mobilization occurred within these bacteria. The selective pressure needed to amplify the resistant, plasmid-bearing strains could easily result from massive use of quinolones and contamination of aquatic environments. It is reasonable to assume that resistance genes then move from the aquatic environment to food animals and eventually to humans.

Concluding Remarks

One of the main clinical problems with quinolones is the development of bacterial resistance. Resistance genes are now being disseminated by plasmids, and the compounds themselves induce resistance through the mutagenic SOS response. Moreover, resistance arises spontaneously, producing mutant subpopulations that can be selectively amplified by traditional treatment strategies. Since many different resistance alleles exist and since resistance develops in a gradual, step-wise manner, many paths can be taken to reach clinical resistance. It is possible to adjust drug concentrations to force bacteria to acquire two or more mutations concurrently for growth. Such mutant-restricting concentrations are likely to be lower for compounds that kill resistant mutants. Thus, new quinolones, and indeed all new antimicrobials, should be developed to be highly lethal with resistant mutants.

Although it is possible to define doses that will restrict the emergence of resistance, changing treatment protocols to protect existing quinolones is difficult. Part of the problem is that mutant-restricting doses are higher than usually needed to cure disease, and they may increase the frequency of toxic side-effects. Consequently, the mutant selection window hypothesis will not be applied until medical philosophy changes from seeking cure to restricting resistance.

Glossary

AHLs Acylhomoserine lactones, quorum signal molecules produced by many Gram-negative bacteria.

autoinducer Molecule produced by a cell that causes self-regulation of pathways within the producing cell above a threshold concentration.

biofilm A community of bacteria associated with a surface.

bioluminescence The production of visible light by living organisms.

biomining The utilization of microorganisms to extract substances from rocks and minerals.

competence The ability of a cell to uptake and utilize DNA from outside sources.

conjugation The physical transfer of DNA from one organism to another.

lantibiotic Antibiotic peptides that contain the amino acid lanthionine.

mucinase Enzyme that degrades the glycoprotein material mucin.

orphan regulator Transcriptional regulators that are not part of a dedicated signal synthase/response system but can interact with the same signal.

synthase A class of enzymes that catalyze biosynthetic reactions of many compounds including quorum signals.

Abbreviations

AHL	Acylhomoserine Lactone
AIP	autoinducing peptide
CSP	competence-stimulating peptide
CT	cholera toxin
DPD	4,5-dihydroxy-2,3-pentanedione
EHEC	enterohemorrhagic <i>E. coli</i>
EPS	exopolysaccharide
GBAP	gelatinase biosynthesis-activating pheromone
HHQ	4-hydroxyl-2-heptyl-quinoline
LEE	locus of enterocyte effacement
PQS	Pseudomonas Quinolone Signal
SAH	S-adenosylhomocysteine
SAM	S-adenosylmethionine
SRH	S-ribosylhomocysteine
TCP	toxin coregulated pilus

Defining Statement

Bacteria utilize numerous mechanisms to monitor and adapt to their external environment. One such mechanism involves the ability to 'count' their local population numbers. Once a specific number of cells, or quorum, is reached, bacteria are able to modify their group behavior through a mechanism known as quorum sensing.

Introduction

Bacterial growth and survival is dependent upon the ability of an organism to sense its environmental conditions and respond to external stimuli. Stimulus can come from a variety of sources including the nutrients available for growth, the presence of secondary metabolites, and the presence of other microorganisms. In the case of nutrients and secondary metabolites, sensor and regulatory proteins exist that affect a change in gene expression as these compounds change concentration. These changes in expression can

Figure 1 Cell density-dependent bioluminescence. As cells multiply, autoinducer concentrations increase. At a critical concentration, they induce synthesis of bioluminescence genes and subsequent light production.

cause bacteria to synthesize new proteins for catabolism in the case of diauxic growth, can lead to the production of extracellular enzymes to liberate nutrients from the environment in the case of starvation, or can cause changes in motility, chemotaxis, or metabolism that allow the bacteria to avoid or eliminate toxic concentrations of a secondary metabolite. In addition to these basic stimulus–response events, bacteria have evolved a mechanism to ‘count’ the local cell population. This process is known as quorum sensing and is mediated by the bacterium’s ability to produce and recognize soluble factors known as quorum signals.

The ability of bacteria to utilize extracellular signals to modify their behavior in a cell density-dependent manner was first described in the early 1970s by Kenneth Nealson, Terry Platt, Woodland Hastings, and Anatol Eberhard. These researchers discovered that the bioluminescent bacterium *Vibrio fischeri* only produced light when bacterial cell numbers were high (Figure 1). They also demonstrated that culture supernatants from high cell density cultures were able to stimulate light production in low cell density cultures. This phenomenon was deemed autoinduction and provided the first clues that bacteria were able to utilize a soluble extracellular signal to monitor population density.

Subsequent work characterized the autoinducer of *V. fischeri* and the genes responsible for its synthesis and detection by the cell. As autoinducer-related genes were studied, it was discovered that many other Gram-negative bacterium contained the genes necessary for autoinducer synthesis and detection. It was demonstrated that autoinducer sensing was dependent upon a critical number of cells in a defined volume. This threshold density of cells was first referred to as a quorum by Clay Fuqua, Stephen Winans, and Peter Greenberg in 1994, and they proposed the term *quorum sensing* to describe this event.

Quorum sensing has rapidly expanded as a field of study, and the discovery of new quorum signaling bacteria as well as new types of quorum signals is increasing at an ever growing rate. Quorum signals in Gram-negative species such as *V. fischeri* were the first to be studied at the genetic and chemical levels; however, a significant amount of work has subsequently been performed with Gram-positive species. It is notable that quorum signal-dependent behavior was observed in Gram-positive bacteria long before the discovery of autoinducers or quorum sensing.

Quorum Signaling in Gram-Positive Bacteria

Although the molecular mechanism was unknown, the physiological effects of quorum signaling were known for a considerably long time in some Gram-positive species. Early work in bacterial genetics determined that some bacterial species were able to participate in horizontal gene transfer through natural competence. Several pioneering studies were done with organisms such as *Streptococcus pneumoniae* well before it was known that the process was quorum signal-dependent. Gram-positive species typically utilize small polypeptide signals as quorum signals. Some of these polypeptides undergo significant modifications to become a soluble extracellular signal (Figure 2).

Streptococcus pneumoniae ComC

S. pneumoniae is a common causative agent of pneumonia, otitis media, meningitis, and several other diseases. Genetic transformation studies were carried out as early as 1928 in this organism by Frederick Griffith. Subsequent work by Avery, McCarty, and MacLeod in 1944 demonstrated that genetic transformation in *S. pneumoniae* was due to uptake of extracellular DNA. Competency

Figure 2 Quorum sensing peptides of *Streptococcus pneumoniae*, *Enterococcus faecalis*, and *Staphylococcus aureus*. Polypeptides ComC, FsrD, and AgrD are modified and exported out of the cell by the ComAB, FsrB, or AgrB transporters. Peptide autoinducers bind to the sensor kinases ComD, FsrC, or AgrC on the cell surface and initiate a phosphorelay to a cytoplasmic response regulator ComE or AgrA, which upregulates cell density-dependent gene expression.

in *S. pneumoniae* is regulated by several factors but is primarily controlled by the competence stimulating peptide (CSP) quorum signal encoded by the gene *comC*.

Genetic competence in *S. pneumoniae* occurs during exponential phase and is initiated by CSP as cell density increases. The 17-amino acid CSP is produced by posttranslational modification of the 41-amino acid precursor peptide ComC and is exported from the cell by the ComAB ABC transporter. When extracellular CSP reaches a threshold concentration due to increasing cell number, it is recognized by the sensor histidine kinase ComD. ComD autophosphorylates and subsequently transfers its phosphate group to the response regulator

ComE. Phosphorylated ComE activates transcription of the alternative sigma factor ComX, which goes on to induce expression of multiple genes involved in DNA uptake and recombination (Figure 2).

This peptide-induced, two-component signal transduction system is typical for Gram-positive quorum signaling circuits and was among the first to be characterized. Induction of competency at high cell density allows *S. pneumoniae* to sample and incorporate genetic material from its environmental counterparts. Surprisingly, *S. pneumoniae* competency permits the organism to take up DNA irrespective of its sequence or host origin. Such behavior gives *S. pneumoniae* the ability to adapt to selective pressures by taking up genes from neighboring cells that may have acquired genes or mutations that allow for enhanced fitness in a specific growth environment.

Enterococcus faecalis FsrB/D

E. faecalis is an opportunistic pathogen that causes endocardial, urinary tract, epidermal, and septic infections in clinical environments. *E. faecalis* is resistant to many common antibiotics and has recently acquired resistance to more modern antibiotic types making it a dangerous human pathogen. *E. faecalis* quorum sensing uses a cyclic lactone-modified peptide signal known as the gelatinase biosynthesis-activating pheromone (GBAP). GBAP is an 11-residue, circular polypeptide closed by a lactone moiety not seen in other Gram-positive-produced cyclic peptides. GBAP is not produced by all *E. faecalis* strains, but its production has been observed in all strains that produce the virulence factor gelatinase.

Originally, the *E. faecalis* GBAP signal was thought to be derived from the C-terminal region of the 212-amino acid FsrB protein. Recent studies have shown that a previously unknown gene, *fsrD*, exists in frame with *fsrB*, and GBAP is derived from FsrD by proteolytic activity of the FsrB protein. The FsrB protein was originally thought to autocatalyze by simultaneously forming and modifying GBAP while exporting it out of the cell. This new data show that the N-terminal region of FsrB is necessary for modification of the previously unknown FsrD peptide to produce the mature GBAP signal.

GBAP is produced maximally at the end of exponential phase in *E. faecalis*. When GBAP concentration reaches a density-dependent threshold, it induces autophosphorylation of the sensor kinase FsrC followed by phosphotransfer to the AgrA protein.

Phosphorylated AgrA is a response regulator that promotes expression of *fsrBD*, *fsrC*, and the virulence factors gelatinase and serine protease (Figure 2). Recent transcriptome analyses of *fsrBD* mutants have shown indirect regulation of genes involved in biofilm formation, surface protein synthesis, and carbon source uptake, as well as direct regulation of an uncharacterized open reading frame. Interestingly, GBAP production is critical for successful colonization in an animal model. It is hypothesized that density-dependent regulation of gelatinase and serine protease by GBAP at the onset of stationary phase allows *E. faecalis* to liberate nutrient sources in the host as they become limiting.

Staphylococcus aureus AgrD

S. aureus is a human pathogen that causes toxic shock syndrome, food poisoning, and epidermal and endocardial infections. The prevalence of antibiotic-resistant *S. aureus* strains has placed it among the most commonly encountered nosocomial infections. *S. aureus* uses the accessory gene regulation (*agr*) system to regulate numerous genes involved in virulence and colonization in a density-dependent fashion via an autoinducing peptide (AIP) signal.

AIP is a thiolactone containing octapeptide ring derived from the 46-amino acid protein AgrD. To form AIP, AgrD is proteolyzed, modified by addition of a thiolactone moiety and exported from the cell by AgrB. Extracellular AIP is detected by the AgrC sensor histidine kinase, which autophosphorylates when bound to AIP. Phospho-AgrC transfers its phosphate group to the response regulator AgrA. The AgrC-AgrA two-component sensor kinase system upregulates the *agrBDCA* operon, establishing a positive feedback loop at sufficient extracellular AIP concentrations. AgrA also induces transcription of the regulatory RNA, RNAIII. RNAIII is an untranslated RNA that upregulates many *S. aureus* virulence factors including toxins and extracellular proteases while down-regulating low-density genes involved in attachment and colonization (Figure 2). Thus, AIP signaling provides *S. aureus* with the ability for transition from colonization and survival at low cell density to pathogenesis and nutrient acquisition at high cell density. This behavior has been hypothesized to allow *S. aureus* to establish a colonization site in the host before virulence factor activity stimulates the host-immune response.

The *S. aureus* quorum sensing and response pathway is very similar to the one found in *E. faecalis*; however, there are notable differences including an increased number of AIP-regulated genes as well as strain specificity of the AIP signal. *S. aureus* AIP has been shown to modulate expression of a larger number of genes, a feat accomplished by induction of RNAIII, and other transcriptional regulators. AIP signaling has also been shown to be strain-specific. There are four known *agrD* specificity groups in *S. aureus* strains. AIP from a single specificity group has been shown to inhibit the AgrC sensor kinase of other groups. Thus, *S. aureus* has acquired a way to compete against other strains of its own species in an infection site when an individual strain reaches a threshold cell density. Therefore, the first strain in a single specificity group to achieve autoinduction of the *agr* pathway will induce its own virulence factor production and block quorum signaling activity in other strains. Quorum sensing systems similar to AIP are present in other *Staphylococcus* species, and these systems exhibit group strain competition as well.

Bacillus subtilis ComX and Phr Peptides

B. subtilis is a soil bacterium that can undergo spore formation or display genetic competence upon entry into stationary phase. Roughly 10% of *B. subtilis* cells entering stationary phase become competent. Competency in this situation is thought to aid *B. subtilis* in DNA repair and contribute to the inheritance of genetic material from *B. subtilis* strains that have successfully grown to high cell density. The decision to become competent or to sporulate is influenced by many factors in a complex regulatory pathway through which quorum signals play a significant part.

The ComX peptide is a 10-amino acid linear peptide derived from a 55-amino acid precursor product of the *comX* gene. The original ComX polypeptide is cleaved, modified, and exported out of the cell by the ComQ protein. Extracellular ComX is sensed by the ComP sensor kinase. Above threshold concentrations of extracellular ComX, ComP phosphorylates the response regulator ComA, which induces the *comS* gene. ComS blocks proteolysis of the transcriptional activator ComK, which upregulates the production of many genes that stimulate competency in the host cell (Figure 3).

A second quorum signaling pathway utilizes multiple proteinaceous pheromone (Phr) signals in a complex regulatory circuit (Figure 3). Phr precursors are proteolyzed and exported out of the cell as linear pentapeptides. Extracellular Phr is taken up into the cell by an ABC oligopeptide transporter. Multiple Phr genes exist and serve to antagonize the activity of several Rap phosphatase enzymes, which regulate many steps along the sporulation and competence pathways. For example, extracellular PhrA enters *B. subtilis* and binds directly to the RapA regulatory phosphatase either preventing it from binding or disassociating it from bound Spo0F-phosphate. RapA bound to the intermediate response regulator Spo0F-phosphate prevents a phosphorelay cascade to the global response regulator Spo0A, thereby preventing sporulation. Thus, increased PhrA levels are one of many factors that allow sporulation to begin by interrupting Spo0F inhibition of Spo0A. In addition to PhrA, there are several other Phr-type signals that are recognized by *B. subtilis* at the end of exponential phase and help direct the organism to specialize in sporulation or competence.

Lactococcus lactis Nisin

L. lactis is a fermentative bacterium commonly used in the dairy industry to produce buttermilk and cheese. *L. lactis* is classified as a lactic acid bacterium as it produces large amounts of lactate upon fermentation of sugars found in dairy products. *L. lactis* produces

Figure 3 Quorum sensing pathways in *Bacillus subtilis*. In the Com system (upper panel), the ComX protein is cleaved, modified, and exported out of the cell by the ComQ transporter. Mature ComX interacts with the ComP sensor kinase that phosphorylates ComA. ComA-phosphate blocks the turnover of the transcriptional regulator ComK, which induces comX and competence gene expression. The Phr system (lower panel) utilizes the PhrA protein, which is cleaved and exported out of the cell using the Sec transport system. Mature PhrA returns to the cytoplasm via an oligopeptide ABC transporter and interferes with RapA binding to Spo0F-phosphate. Spo0F-phosphate can then phosphorylate the response regulator Spo0A, which induces sporulation genes.

the antimicrobial peptide nisin, which was discovered in 1928 due to its ability to inhibit growth of other lactic acid bacteria. In 1988, nisin was approved by the FDA for use as a preservative agent in the food industry.

Nisin is a Class I bacteriocin or lantibiotic characterized by its small size and the inclusion of the amino acids lanthionine and -methyllanthionine as well as other dehydrated amino acids. Nisin is bactericidal and forms pores in bacterial membranes. This activity is especially effective against other Gram-positive bacteria where cell membrane perforations immediately cause a loss of membrane integrity.

Despite its role as an antimicrobial agent, nisin also serves as a density-dependent signal for *L. lactis*. Nisin is a highly modified 34-amino acid product of the 57-amino acid polypeptide NisA. NisA is modified and exported out of the cell by the NisBCT membrane-associated complex. Upon leaving the cell, modified NisA is cleaved to form nisin by the extracellular NisP protease. Damage of the parent cell membrane by nisin is prevented by the production of several proteins that block nisin activity at the cell surface. Extracellular nisin concentration is sensed by the NisK sensor kinase, which phosphorylates and activates the NisR response regulator. Nisin production is maximal during early stationary phase growth. NisR promotes expression of the *nisA* gene as well as genes that encode for proteins that block nisin activity at the cell surface, allowing for a positive feedback loop to upregulate nisin production as *L. lactis* enters stationary phase. Interestingly, the production of nisin demonstrates the ability of a compound to act as both a quorum signal and an antimicrobial agent. This type of dual function by an extracellular compound provides *L. lactis* with an efficient and powerful quorum signaling system that might provide a notable competitive advantage in polymicrobial environments.

Acylhomoserine Lactone (AHL) Quorum Signals in Gram-Negative Bacteria

The distribution of Gram-negative and Gram-positive bacterial species throughout the world is highly similar. Both types of organisms inhabit nearly every known niche on the planet and are involved in biogeochemical mineral cycles, biochemical degradation, disease, and the production of a staggering number of extracellular small molecules. While Gram-positive species have largely evolved to utilize polypeptide quorum signals that depend on cell-surface receptors, Gram-negative bacteria often utilize soluble signals known as AHLs. Many AHLs are able to pass through the lipid bilayer and are therefore able to interact with cytoplasmic regulatory proteins; thus, AHLs do not rely on the phosphorelay cascades that Gram-positive quorum sensing

pathways commonly use. Both types of signals are effective due to their stability and solubility in environments colonized by the organisms that synthesize them.

V. fischeri LuxI/R

As mentioned previously, quorum signaling was discovered in the luminescent marine bacteria *V. fischeri* and *Vibrio harveyi*. In the early 1970s, researchers observed that supernatants from stationary phase cultures could be added to cells at low density and trigger light production. This suggested the presence of an autoinducing compound made in later phases of *V. fischeri* and *V. harveyi* growth. Further study determined that the factor in spent medium was relatively species-specific and dependent on cell density rather than the nutritional status of the cells. In 1981, the *V. fischeri* autoinducer was purified and determined to be the AHL 3-oxo-hexanoyl-HSL (3OC₆-HSL). A variety of AHL compounds have been characterized from other organisms and are collectively referred to as autoinducer-1 (AI-1).

V. fischeri can be found free-swimming and can also participate in a symbiotic relationship with the Hawaiian bobtail squid *Euprymna scolopes*. *V. fischeri* colonizes a cavity on the squid host known as the light organ. *V. fischeri* receives nutrients from the host in the light organ and emits light as its population density and AI-1 concentrations increase. Luminescence from the light organ of *E. scolopes* is thought to help the squid evade predation by masking the organisms' shadow in shallow water. *V. fischeri* has also been observed to enter symbiotic relationships with other marine organisms such as the fish *Monocentris japonicus* where a *V. fischeri*-dependent light organ is used to attract a potential mate.

The *V. fischeri* LuxI protein synthesizes 3-oxo-C₆-HSL from S-adenosylmethionine (SAM) and acylated acyl carrier protein. Once synthesized, 3OC₆-HSL freely diffuses across the membranes and out of the cell. At a particular density, a critical concentration of AI-1 is reached that stimulates AI-1 to interact with and activate the response regulator LuxR. Activated LuxR promotes transcription of the *luxR* gene as well as the *luxICDABEG* operon, which serves to produce light and generate more AI-1 (Figure 4). Thus, a positive feedback loop develops at sufficient cell densities, which allows for a substantial increase in light production. AI-1 exists in many Gram-negative species and is thought to function as an intraspecies-specific signal.

Figure 4 Quorum sensing in *Vibrio fischeri*. The LuxI-produced 3OC₆-HSL diffuses out of the cell until it reaches sufficient concentration to induce the LuxR response regulator. 3OC₆-HSL-LuxR induces expression of the *luxR* and the *luxICDABEG* genes, which increase synthesis of 3OC₆-HSL as well as proteins involved in bioluminescence. At low cell density, C₈-HSL, produced by the *AinS* gene, provides initial activation of LuxR by direct activation as well as by inhibiting LuxO, preventing the *litR* gene product from inducing the *luxR* gene, thereby increasing levels of *luxR* transcript in the cell.

Recently, a second AHL quorum signal has been identified in *V. fischeri* and has been shown to function as part of a regulatory network in combination with 3OC₆-HSL and a third signal, the furanosyl borate diester signal AI-2 (which will be discussed later). This AHL signal is *N*-octanoyl HSL (C₈-HSL) and is produced by AinS (Figure 4). C₈-HSL regulates luminescence at low culture densities by relieving negative regulation of the LuxR protein due to inactivation of the transcriptional regulator LuxO. Inactivation of LuxO allows upregulation of *litR*, whose gene product serves to activate *luxR* transcription. C₈-HSL also interacts with LuxR directly, allowing for initial activation of the *luxICDABEG* operon.

Pseudomonas aeruginosa Las/Rhl AI-1 System

P. aeruginosa is a Gram-negative bacterium commonly isolated from soil environments, which is frequently used as a model organism to study quorum sensing. *P. aeruginosa* is an opportunistic pathogen that can cause an array of infections in immunocompromised individuals, most notably those inflicted with the heritable disease cystic fibrosis. Many of the genes necessary for infection, nutrient acquisition, virulence factor production, and biofilm growth are regulated by the concentrations of two AHL signals produced by LasI and RhlI. Due to its effects on virulence factor production, interference with quorum signaling in *P. aeruginosa* has been proposed as a therapeutic strategy. This novel approach to antimicrobial therapy in a notoriously antibiotic-resistant organism makes further study of quorum sensing in *P. aeruginosa* increasingly important.

The LasI protein synthesizes the signal *N*-(3-oxododecanoyl)-L-HSL (3OC₁₂-HSL). 3OC₁₂-HSL interacts with the LasR response regulator, which upregulates the expression of multiple genes involved in virulence such as the *lasB* protease as well as the *lasI* gene itself, establishing 3OC₁₂-HSL as an autoinducer. While 3OC₁₂-HSL is diffusible, it can also partition into the cell membrane and has been shown to be exported by efflux pumps in *P. aeruginosa*.

The LasR-3OC₁₂-HSL complex serves to upregulate a second AHL-dependent system by inducing expression of *rhlR* (Figure 5). RhlI synthesizes *N*-butyryl-L-HSL (C₄-HSL), which interacts with the response regulator RhlR to regulate numerous genes including those involved in secondary metabolite production, as well as the *rhlI* gene that establishes a second AHL autoinduction loop. C₄-HSL-dependent regulation overlaps with 3OC₁₂-HSL-mediated regulation in the control of several genes such as

Figure 5 Quorum sensing in *Pseudomonas aeruginosa*. 3OC₁₂-HSL produced by the LasI synthase interacts with the LasR transcriptional regulator, which upregulates *lasI*, *lasB*, *vqsR*, and *pqsH*. 3OC₁₂-HSL also interacts with the orphan transcriptional regulator QscR to repress *lasI* expression. PqsH produces the quinolone signal PQS that is transported between cells via outer membrane vesicles. PQS induces expression of the *rhlR* gene whose product induces expression of the *rhlI* synthase gene as well as several other virulence factors when induced by the RhlI-produced C₄-HSL signal.

the extracellular protease encoded by the *lasB* gene. It is notable that 3OC₁₂-HSL inhibits the interaction of C₄-HSL with its response regulator RhlR while inducing expression of the *rhlR* gene. This interaction serves to maintain levels of C₄-HSL low until RhlR concentration increases to levels sufficient to interact with the low levels of C₄-HSL produced in late exponential phase. Thus, the activation of the C₄-HSL–RhlI feedback loop becomes functional only after LasR–3OC₁₂-HSL-dependent regulation has occurred.

Both quorum signals in *P. aeruginosa* ultimately serve to regulate the expression of over 300 genes involved in diverse pathways. Such regulation is not achieved by the LuxR-like LasR and RhlR response regulators alone. For example, LasR induces expression of the *vqsR* gene, whose product upregulates genes involved in virulence factor production and quorum signaling. Apart from downstream regulators induced by LasR or RhlR, 'orphan' LuxR-type regulators that do not have a cognate LuxI-type produced AHL signal have been discovered. QscR is a LuxR-type response regulator that binds the promoters of several genes in the presence of the LasI-generated signal 3OC₁₂-HSL. Apart from these interactions, QscR has been shown, at least indirectly, to repress *lasI* expression (and was in fact named for this activity, quorum signaling control repressor). The manner in which QscR represses *lasI* expression is unclear but has been hypothesized to involve heteromultimerization of QscR and LasR. Another hypothesis is that QscR binding to 3OC₁₂-HSL prevents this AHL from coming in contact with its cognate regulator LasR. Interestingly, QscR has also been shown to be more promiscuous in AHL binding than either LasR or RhlR, suggesting a role in interspecies AHL sensing. Ultimately the HSL-dependent quorum signaling network combined with orphan response regulators contribute a great deal to global gene regulation in *P. aeruginosa*.

***Agrobacterium tumefaciens* Tra System**

A. tumefaciens is a Gram-negative soil bacterium, which is the causative agent of crown gall disease in plants. Some *A. tumefaciens* strains carry a Ti (tumor-inducing) plasmid that contains the LuxI/R-type quorum signaling genes *traI* and *traR*. The Ti plasmid also carries genes that encode for specific plant hormones. After conjugation of the Ti plasmid from *A. tumefaciens* to the host nucleus, plants synthesize these hormones that then stimulate cell proliferation and tumor formation.

Free-swimming *A. tumefaciens* move throughout the soil by flagellar motility and search for susceptible hosts by chemotaxis toward metabolic intermediates released from wounded plants. Upon contacting the host, *A. tumefaciens* produces cellulose fibrils as well as attachment proteins to anchor it to host tissue. After attachment, *A. tumefaciens* *vir* (virulence) genes are induced by host-derived compounds that in turn activate synthesis of a secretion apparatus that directs translocation of the Ti plasmid from *A. tumefaciens* into the host. Ti plasmid-encoded hormones then cause cell proliferation and tumor formation. The Ti plasmid also contains genes whose products direct synthesis of opines. Opines are specialized amino acids that *A. tumefaciens* uses as a growth substrate. There are at least two known classes of opine-encoding genes, octopine and nopaline, and *A. tumefaciens* strains or pathovars can be classified by which genes are present on the Ti plasmid. These plasmid-borne genes not only direct host synthesis of opines, but contain opine catabolism genes, allowing *A. tumefaciens* to use opines as a source of carbon and energy.

A. tumefaciens uses the TraI/R quorum sensing system to regulate conjugation of the Ti plasmid between *A. tumefaciens* strains. The *traI*/R quorum signaling genes are similar to the *luxI*/R genes from *V. fischeri*, but there are key differences in regulation. In octopine-utilizing pathovars, the *A. tumefaciens* transcriptional activator OccR is induced by the presence of the opine octopine. OccR positively regulates expression of *traI*, whose product synthesizes the *N*-(3-oxo-octanoyl)-LHSL (3OC₈-HSL) quorum signal. In nopaline-utilizing pathovars, the opine agrocinopine inactivates the *traR* repressor AccR. This interaction also increases expression of *traI* in the cell (Figure 6).

Increased *traI* expression in the cell ultimately leads to an increase in 3OC₈-HSL. As 3OC₈-HSL reaches a critical threshold, it induces *traR* expression. When TraR is bound to 3OC₈-HSL, it induces *traI*, establishing an autofeedback loop. Activated TraR also induces expression of the *trb* operon, which produces the mating pore between two *A. tumefaciens* cells; the *tra* operon, which helps mobilize the Ti plasmid; and the *traM* gene. TraM inactivates TraR, thus providing a means for *A. tumefaciens* to downregulate the quorum signal-dependent synthesis of the conjugation apparatus after it has begun. The *A. tumefaciens* TraI/R system, while similar to the LuxI/R system of *V. fischeri*, has an additional level of regulation dependent on host opine production ensuring that quorum signal-controlled induction of conjugation does not occur prematurely outside of a compatible host. This system serves as an elegant example of interspecies-dependent cues having regulatory input in bacterial signaling pathways.

***Pantoea stewartii* EsaI/EsaR System**

The Gram-negative bacterium *P. stewartii* is the causative agent of Stewart's bacterial wilt and leaf blight in sweet corn and maize. *P. stewartii* is spread by infected populations of the corn beetle, *Chaetocnema pulicaria* that introduces the bacterium into the xylem and intercellular leaf spaces of the plant during feeding. Infection by *P. stewartii* results in wilting due to colonization of the xylem and formation of water-soaked lesions due to bacterial growth within young leaves. Buildup of large amounts of exopolysaccharide (EPS) results in vascular occlusion of plant tissue. EPS secreted by *P. stewartii* is the principal virulence factor and is part of a multistep invasion process.

P. stewartii secretes EPS in a cell density-dependent fashion. Biosynthesis of EPS is encoded by the *cps* gene cluster, while regulation of EPS synthesis is mediated partly by the EsaI/R quorum signaling system. The EsaI/R system also controls the Hrp (hypersensitivity and pathogenicity) regulon. *P. stewartii* requires the Hrp type III secretion system for infection of the intercellular leaf spaces and formation of the characteristic watersoaked lesions.

Figure 6 Quorum sensing in *Agrobacterium tumefaciens*. (a) A plant infected with *A. tumefaciens* displaying a characteristic tumor. (b) Inside the tumor, proliferating host cells that carry the Ti plasmid produce an opine nutrient for *A. tumefaciens*. (c) Octopine-type opines interact with the OccR transcriptional regulator causing it to upregulate octopine catabolism genes as well as induce *tral* expression. *Tral* synthesizes the 3OC₈-HSL signal that interacts with the TraR protein, causing it to further induce *tral* expression and the *trb* and *tra* operons utilized in conjugation. 3OC₈-HSL-TraR also induces the *traM* gene, whose product inhibits TraR activity.

The *cps* genes are regulated by the Rcs (regulator of capsule synthesis) two-component signal transduction system that detects environmental signals. The Rcs system is composed of the RcsB cytoplasmic response regulator and the RcsC transmembrane sensory protein. It is thought that for complete induction of the *cps* genes, another protein (RcsA) may be required. Also, in the absence of AHLs, EsaR negatively regulates the *cps* genes.

Interestingly, the AHL synthase gene *esaI* is constitutively expressed and is not autoregulated by *esaR* like many other *luxI/R*-type genes, while *esaR* is autorepressed by the EsaR protein. *Esal* synthesizes 3-oxo-C₆HSL and small amounts of 3-oxo-C₈HSL. Mutants in *esaI* do not produce AHLs or EPS and are avirulent. In contrast, *esaR* and *esaI/R* double mutants demonstrate a constitutive hypermucoidy phenotype and are less virulent than the wild type. The hypermucoidy mutants of *P. stewartii* also appear impaired in attachment compared to wild-type *P. stewartii*. This indicates the importance of quorum control of pathogenicity factors in *P. stewartii* as production of EPS at an incorrect location and phase of infection renders the cells avirulent and unable to colonize the host.

Acidithiobacillus ferrooxidans AfeI/R

A. ferrooxidans is a Gram-negative acidophilic chemolithotrophic bacterium that is commonly found in multispecies biofilms on mineral surfaces such as pyrite and elemental sulfur in rock and soil. *A. ferrooxidans* catalyzes the oxidation of iron and sulfur yielding sulfuric acid. It is a causative agent of acid mine drainage, which can lead to groundwater contamination. The ability of *A. ferrooxidans* to dissolve mineral structures can also be used in 'biomining' where acid solubilization of rocks and soil can release minerals such as copper and gold that are used in industrial applications. This process, also known as bioleaching, is a slower yet more energy efficient and environmentally containable process as opposed to traditional smelting of ores to release rare metals.

To date, AHL quorum signaling in *A. ferrooxidans* is relatively poorly understood. Recent studies have determined that *A. ferrooxidans* produces nine different medium to long-chain (C8–C16) AHL signals containing an even number of carbons. The AHL signals also contain either oxo or hydroxyl modifications at the third carbon of the molecule. At this time, only one AHL synthesis gene, *afel*, has been identified and characterized, but another open reading frame has been hypothesized to be an AHL synthase due to its sequence homology to the AHL synthase *hdtS* from *Pseudomonas fluorescens*.

AfeI is similar to *LuxI* of *V. fischeri* and produces five different AHLs when expressed in an AHL-lacking *Escherichia coli* strain. Immediately downstream of the *afel* gene in *A. ferrooxidans* is the *luxR* homologue *afeR*. Transcriptional studies show that *afel* and *afeR* transcripts are present and *afel* transcript levels increase relative to increases in AHL concentration. Downstream regulatory targets for *AfeR* in *A. ferrooxidans* have not been fully determined, but it has been shown that *afel* transcripts are strongly induced during phosphate-limiting conditions. It has also been shown that there are differential increases of specific AHL molecules during growth in sulfate, thiosulfate, or iron-containing medium. This data suggest that the type of AHL signal produced may be influenced by the growth substrate as well as cell density. The fact that *A. ferrooxidans* is often found in multispecies biofilms and produces a variety of AHL types could also suggest a role for *A. ferrooxidans* in modulating density-dependent expression of other species in response to growth substrates *in situ*.

The Study of AHL-Dependent Signal Pathways Demonstrated the Presence of Another Quorum Signal AI-2

V. harveyi and the LuxS-Produced Signal AI-2

Previously we discussed the discovery of quorum signaling in the luminescent marine bacteria *V. fischeri*. Further work with *V. fischeri* identified and characterized the *LuxI/R* regulatory circuit and the AI-1 HSL signal. However, determining the nature of the density-dependent signal in the closely related luminescent bacterium *V. harveyi* yielded different results. *V. harveyi* luminescence is density-dependent, inducible by spent culture medium, and is dependent upon a 3OHC₄-HSL. Despite these similarities, genes homologous to *luxI* and *luxR* were not found on the *V. harveyi* chromosome.

Mutational analysis determined that *V. harveyi* 3OHC₄-HSL was produced by the AHL synthase proteins *LuxL* and *LuxM*. It is not clear which protein is the actual synthase, but the presence of both is necessary for 3OHC₄-HSL production. Neither gene has significant sequence homology to *V. fischeri luxI* but appear to carry out similar reactions to synthesize 3OH-C₄-HSL. It was also found that a *luxN* gene encoded for a sensor kinase protein, which was necessary to sense extracellular AHLs. This mechanism is reminiscent of Gram-positive AIP sensors. *LuxN* was later shown to autophosphorylate at low 3OHC₄-HSL concentrations and transfer phosphate to the *LuxO* response regulator via the intermediate *LuxU*. *LuxO*-phosphate represses expression of the *luxCDABE* luminescence operon, ensuring that light production is turned off at low AHL concentrations. Knockout mutants in either the *luxLM* synthesis genes or the *luxN* sensor kinase gene did not completely abrogate density-dependent expression of luminescence genes. This suggested the presence of a second quorum signaling system in *V. harveyi*.

The same mutational study that characterized the *luxL*, *luxM*, and *luxN* genes also showed that deletions in the sensor kinase *luxQ* and periplasmic binding protein *luxP* were necessary for density-dependent luminescence independent of the 3OHC₄-HSL signal. These proteins were shown to be part of a second sensory mechanism in *V. harveyi*. Reporter strains were created using the *luxP* and *luxQ* genes to detect a second signal. Initial biochemical characterizations revealed that a second signal could activate the *luxQP* reporter strains, and this signal was named AI-2. Surprisingly, AI-2 is produced by several other species of bacteria and the *luxS* gene responsible for AI-2 synthesis was identified in *V. harveyi*, *E. coli*, and *Salmonella typhimurium* shortly after.

LuxS synthesizes AI-2 as part of a detoxification reaction in the activated methyl cycle. Methyl transfer reactions are vital in bacterial metabolism and are dependent on the methyl donor SAM. SAM is converted into the toxic Sadenosylhomocysteine (SAH) molecule and can be detoxified by two different mechanisms. The first mechanism utilizes the SAH hydrolase gene, which hydrolyzes SAH into the SAM precursors adenosine and homocysteine. Organisms that do not produce AI-2, such as *P. aeruginosa*, utilize this pathway. The second mechanism utilizes the *Pfs* enzyme, which hydrolyzes SAH into adenosine and S-ribosylhomocysteine (SRH). Homocysteine is removed from SRH leaving 4,5-dihydroxy-2,3-pentanedione (DPD) in a reaction catalyzed by the *LuxS* enzyme; DPD spontaneously cyclizes to form the furanosyl diester AI-2. Recent work has shown that AI-2 in *V. harveyi* incorporates boric acid into its structure, the first known biological use of this molecule. To date, it does not appear that boron-containing AI-2 signals are used outside of the *Vibrio* genus and that AI-2 molecules lacking boron function as signals in other bacteria.

As mentioned above, AI-2 is recognized by the sensor kinase *LuxQ* via the periplasmic AI-2-binding protein *LuxP*. When a threshold concentration of AI-2 is reached, *LuxQ* changes from a kinase to a phosphatase, removing the phosphate from its downstream target *LuxU*. As *LuxU* is dephosphorylated, it removes phosphate from the *LuxO* protein. Unphosphorylated *LuxO* loses the ability to repress the *luxCDABE* operon, and luminescence genes are then activated by the transcriptional activator *LuxR*, which has no homology to the *V. fischeri LuxR* regulator. Thus, the *V. harveyi* quorum-signaling pathway utilizes the input of two separate density-dependent signals that act on the central regulator *LuxO*. This pathway is similar to the *Vibrio cholerae* quorum-signaling pathway described in Figure 7.

It is notable that AI-2 synthesis is directly linked to a key metabolic pathway in organisms that carry the *luxS* gene. Because of this link, it is hypothesized that *LuxS* production is an indicator of the metabolic status of the organism as well as its population density. This could be similar to the differential AI-1-type signal production seen in *A. ferrooxidans*. It should also be mentioned that only two genomes sequenced to date contain genes for both SAH detoxification mechanisms, and this phenomenon may indicate a point of divergence in bacterial evolution.

Figure 7 Quorum sensing in *Vibrio cholerae*. CqsA and LuxS produce CAI-1 and AI-2, respectively. CAI-1 interacts with the CqsS sensor phosphatase, and AI-2 interacts with the LuxQ sensor phosphatase via the AI-2-binding protein LuxP. Both phosphatases remove phosphate from the LuxO protein. Dephosphorylated LuxO is inactive and no longer induces expression of the small RNAs Qrr1–4, which served to repress hapR expression. Translation of HapR induces expression of the hapR protease gene and represses expression of genes involved in virulence and biofilm formation.

AI-2 and *V. cholerae*

V. cholerae is a free-swimming marine bacterium and is the causative agent of cholera in humans. *V. cholerae* is commonly found attached to the surface of zooplankton in the ocean. Cholera outbreaks can be associated with zooplankton blooms near human populations. During the course of disease, *V. cholerae* is ingested and survives the low pH of the stomach to colonize the host small intestine. During colonization, *V. cholerae* uses motility and mucinase to penetrate the mucus layer of the intestine and gain access to the underlying epithelial cell layer.

Currently, *V. cholerae* strain El Tor is the cause of a global cholera pandemic in underdeveloped nations. *V. cholerae* El Tor contains the HapR regulator that represses expression of virulence factors such as the cholera toxin (CT) and the cholera toxin coregulated pilus (TCP). TCP and CT have been shown to be critical for *V. cholerae* host colonization in animal models. The HapR regulator is acted upon by quorum signals in *V. cholerae* El Tor and links the quorum signaling pathway to virulence factor production. Previous pandemic strains of *V. cholerae* contain mutations within the *hapR* gene and are not considered to be responsive to quorum signaling.

V. cholerae contains a quorum sensing system that is similar to *V. harveyi*. However, one of the autoinducer signals as well as the genes regulated by quorum signaling are different in *V. cholerae*. In *V. cholerae*, the AI-2 signal and the recently characterized signal (S)-3-hydroxytridecane-4-one (CAI-1) are recognized by the sensor kinases LuxQ and CqsS, respectively (Figure 7). In low cell density conditions, LuxQ and CqsS act as kinases that phosphorylate LuxU, which then transfers its phosphate to LuxO much like the pathway in *V. harveyi*. Phosphorylated LuxO induces the expression of four small regulatory RNAs (sRNAs) known as Qrr1–4. These sRNAs interact with the sRNA chaperone protein Hfq and induce expression of an uncharacterized regulatory gene (*vca0939*) as well as destabilize the mRNA for *hapR*, the master quorum signaling regulator. When *hapR* is repressed, virulence genes are upregulated, due in part to removal of HapR repression of the *tcpP* gene, which encodes the signaling protein TcpP that induces expression of the ToxT regulator. ToxT induces expression of the virulence factors TCP and CT, so in conditions of low cell density and autoinducer concentrations, virulence and biofilm development genes are upregulated. TCP allows for cell–cell aggregation of *V. cholerae* as well as attachment to the host. CT activity causes epithelial cells to excrete large amounts of water, ultimately causing the host to rapidly expel its intestinal contents, one of the hallmark symptoms of a *V. cholerae* infection.

At high cell densities, LuxQ and CqsS act as phosphatase in the same fashion as LuxQ and LuxN in *V. harveyi*. LuxQ and CqsS ultimately cause the dephosphorylation of LuxO, which causes expression of the Qrr sRNAs to be decreased. As Qrr sRNA expression decreases, *hapR* is upregulated. HapR blocks expression of virulence factors and genes involved in biofilm development. HapR also induces expression of the *hap* gene, which encodes for a protease that aids *V. cholera* in release from a colonized area. In *V. cholerae*, density-dependent signals provide the cell with a method to change cell behavior from a colonizing, scavenging lifestyle at low density, to a motile, migratory lifestyle at high cell density. Interestingly, this change in behavior occurs at a time when pathogenic effects of *V. cholerae* are inducing the host to expel large amounts of intestinal contents, thus allowing the freshly liberated *V. cholerae* to return to a free-swimming lifestyle. It is also interesting that quorum signal-utilizing pathogens such as *S. aureus* and *P. aeruginosa* upregulate virulence factors at high density to form persistent infections, whereas *V. cholerae* downregulates virulence and rapidly leaves the host once high population density has been achieved.

E. coli, *S. typhimurium*, and AI-2

The Gram-negative enteric bacteria *E. coli* and *S. typhimurium* both grow in the lower intestine of mammals. While certain *E. coli* strains are pathogenic, many strains are part of the normal flora. *S. typhimurium* is the causative agent of typhoid fever and, while closely related to *E. coli*, is often a more transient inhabitant of the gastrointestinal tract. Both of these bacteria produce AI-2 using the LuxS enzyme, with maximum production occurring at mid-exponential phase growth. Surprisingly, extracellular AI-2 concentrations drop rapidly as either organism enters stationary phase. This suggests a mechanism for AI-2 sequestration or degradation.

AI-2 has been shown to regulate several genes in both *E. coli* and *S. typhimurium*. These genes include the *lsrACDBFGE* operon, the *lsrK* kinase gene, and *lsrR* whose product represses the *lsr* operon. In both organisms, AI-2 is produced during growth and accumulates outside of the cell. When threshold AI-2 concentrations are reached, AI-2 is imported by the LsrABCD ABC transporter. After import into the cell, AI-2 is phosphorylated by the LsrK kinase and catabolized by the LsrE, LsrF, and LsrG proteins. The products of phospho-AI-2 catabolism have not been characterized at the time of this writing. While the import and catabolism of AI-2 by these organisms is regulated in a density-dependent fashion, it is unclear if these organisms utilize AI-2 to direct group activities. The simplest explanation is that AI-2 is produced as a metabolite during SAH detoxification in the activated methyl cycle and is taken as backup to be utilized as a carbon source later in the growth phase.

Despite the possibility that *E. coli* and *S. typhimurium* may utilize AI-2 only as a metabolite, production of AI-2 by these bacteria may affect gene expression of other AI-2 responsive bacteria in polymicrobial environments. In a 2005 *Nature* paper, Karina Xavier and Bonnie Bassler demonstrated that when *V. harveyi* or *V. cholera* were grown in coculture with *E. coli*, they were subject to interference of AI-2-mediated signaling due to the ability of *E. coli* to respond to higher AI-2 concentrations. As *E. coli* cell density increased, it was able to remove AI-2 from the culture and reduce expression of AI-2-dependent genes in either *Vibrio* species. At low cell densities, premature induction of AI-2-regulated genes was observed in *V. harveyi*, as the AI-2 produced by *E. coli* increased the AI-2 concentration that *V. harveyi* would normally encounter at that cell density. It is apparent from these studies that AI-2 signal turnover can have substantial effects on multispecies interaction even if AI-2 does not appear to have a strong role in quorum-signal-dependent behavior in a single species.

luxS-Dependent Interactions in Human Oral Bacteria

The human oral cavity is populated by over 300 different bacterial species. There are several distinct niches within the oral cavity (tooth enamel surface, epithelial cell surface, and the subgingival space), all of which can be colonized by bacteria growing in multispecies biofilms. Many species isolated from the oral cavity contain the *luxS* gene, and in several cases, density-dependent AI-2-mediated behavior has been observed in single and multispecies cultures.

Streptococcus mutans is a common inhabitant of the oral cavity and is the causative agent of dental caries. Merritt and Shi in a 2003 *Infection and Immunity* paper demonstrated that biofilm formation by *S. mutans* was altered in a *luxS* mutant. The *S. mutans luxS* mutant formed a biofilm with denser cell aggregates that was more resistant to detergent and antibiotics. While growth rate and acid production did not appear to be altered in the *luxS* mutant, it was not determined whether extracellular AI-2 concentration or the effects of impeded SAH detoxification were responsible for the mutant phenotype.

Direct AI-2-dependent interaction in oral bacteria was reported in 2003 by McNab and Lamont in the *Journal of Bacteriology*. The researchers demonstrated that *Streptococcus gordonii* and *Porphyromonas gingivalis* formed significantly dense biofilm structures if either organism contained a functional *luxS* gene. Simultaneous *luxS* mutations in both species led to diminished biofilm formation, suggesting that *luxS*-dependent AI-2 formation from one organism can complement the ability of the other to form more fully developed multispecies biofilms.

This phenomenon is similar to another described in a 2004 *Proceedings of the National Academy of Sciences* paper by Eglund and Kolenbrander. In that study, *S. gordonii* was shown to upregulate production of amylase only when grown in close proximity to *Veillonella atypica*. This interaction was hypothesized to be dependent on an increase in local concentration of a diffusible signal when the bacteria grow in close proximity to one another. This data suggest that signal production by *S. gordonii* alone is insufficient to upregulate amylase under the conditions tested, and the presence of another signal-producing organism is also necessary. AI-2 is hypothesized to be the diffusible signal in this system, but this has not been unequivocally shown. Both of these cases demonstrate that extracellular signal concentrations are critical to modulate behavior in each organism. This is notable because in the case of *S. mutans* and other literature discussing *luxS*-dependent signaling events, it is often unclear if the phenotypes observed are due to actual AI-2-dependent signaling, or due to metabolic effects caused by an impediment of SAH detoxification.

AI-2-dependent quorum signaling has also been observed in the opportunistic pathogen *Aggregatibacter actinomycetemcomitans*. LuxS activity or exogenous AI-2 addition to cultures have been shown to cause differential expression of iron uptake genes as well as leukotoxin production. AI-2 production by *A. actinomycetemcomitans* has also been shown to complement *luxS*-dependent gene expression in a *P. gingivalis luxS* mutant when cocultured. A 2007 *Infection and Immunity* paper by Shao and Demuth demonstrated that *A. actinomycetemcomitans* is impaired for biofilm production in a *luxS* mutant. Subsequent complementation of *luxS* by *P. aeruginosa sahH* seems to restore the ability to detoxify SAH in the activated methyl cycle, but exogenously added AI-2 was necessary to restore the biofilm phenotype. While *sahH* transcripts were present in the complemented strain, it is not clear if SahH was produced and able to detoxify SAH. Despite the unknown status of SahH activity, this data strongly suggest that AI-2 serves as a signal for community behavior in *A. actinomycetemcomitans*, and not just a metabolite produced in the activated methyl cycle.

AI-2 signaling is responsible for density-dependent regulation of genes in several well-characterized systems. At this time, over 153 separate eubacterial genomes contain a *luxS*-like sequence according to the Kyoto Encyclopedia of Genes and Genomes (KEGG) database. It is evident that in the case of *Vibrio* species and several inhabitants of the mammalian oral cavity, AI-2-dependent signaling plays a critical part of these organisms' lifestyle. However in many organisms, the presence of a *luxS* gene does not correlate to density-dependent signaling behavior. The 'other' function of LuxS as part of the activated methyl cycle is an important component of metabolism, and it cannot be assumed at this time that phenotypic changes in *luxS* knockouts are exclusively due to AI-2 signaling and not disruption of SAH detoxification.

Other Types of Quorum Signals

In addition to AI-1, AI-2, and peptide autoinducer signals, there are many other types of quorum signals utilized by bacteria. We are only beginning to understand the molecular aspects of these systems, and in some cases the structure of the signal is not known.

The AI-3/Epinephrine Quorum Signaling System

E. coli is a common inhabitant of the human lower intestine. Recently, strains have evolved that carry multiple virulence factors giving rise to enterohemorrhagic *E. coli* (EHEC) strains such as *E. coli* O157:H7. EHEC strains are notorious for their ability to cause hemorrhagic colitis and hemolyticuremic syndrome. As EHEC colonizes the lower intestine, it forms lesions on host epithelial tissue and produces a Shiga toxin. A majority of the genes involved in attachment, lesion formation, and virulence exist on the EHEC chromosome in a pathogenicity island known as the locus of enterocyte effacement (LEE).

Expression of *LEE* genes is regulated by factors present in the native *E. coli* chromosome as well as factors encoded on *LEE* itself. In addition to these, some *LEE* genes appear to be regulated in a cell density-dependent fashion. Preliminary studies of a *luxS* EHEC mutant showed changes in *LEE* gene expression, indicating that AI-2 may play a role in regulation. However, the addition of exogenous AI-2 to the *luxS* mutant did not complement *LEE* gene regulation. This data suggested that *LEE* gene regulation was subject to metabolic changes observed in the *luxS* mutant. It was then shown that *LEE* gene regulation could be complemented by concentrated extracts from *luxS* mutant supernatants, and that an unidentified compound chemically different from AI-2 was synthesized at a low rate in the *luxS* mutant. *LEE* gene expression phenotypes were also restored in a *luxS* mutant strain that was complemented with the SAH hydrolase enzyme from *P. aeruginosa*. This experiment determined that homocysteine formation by either the SAH hydrolase enzyme or LuxS restored *LEE* gene expression. This suggested the presence of an inducer deemed, AI-3, whose biosynthesis utilizes precursors from the activated methyl cycle.

Other studies indicated that *LEE* gene expression could be influenced by epinephrine and norepinephrine hormones from the host, and it was hypothesized that AI-3 might resemble epinephrine/norepinephrine due to similarities in chemical properties. At this time, the structure of AI-3 is still unclear; however, the addition of exogenous epinephrine/norepinephrine induces similar sets of genes when compared to addition of impure AI-3 extracts. It has also been shown that AI-3 and epinephrine induce *LEE* genes as well as other targets and are dependent on the sensor histidine kinase QseC. EHEC are likely to come in contact with epinephrine/norepinephrine in the lower intestine during colonization as norepinephrine is produced by neurons in the enteric nervous system and epinephrine is secreted as a systemic response to host stress during EHEC disease progression. The discovery of QseC as a receptor for both a host-produced hormone and a bacterially produced quorum signal is astounding and contains many implications for future discoveries in quorum signaling as well as evolution between the bacterium and the host.

Bradyrhizobium japonicum Bradyoxetin Signal

Bradyoxetin is produced by the nitrogen-fixing soil bacterium *B. japonicum*. Genes involved in biosynthesis are unknown at this time, although the biosynthetic pathway is likely similar to that of the siderophore mugenic acid. Similar to siderophores, bradyoxetin production is regulated by Fe^{3+} concentration as well as cell density with bradyoxetin produced maximally at high cell densities or at low Fe^{3+} concentrations. At high cell densities, bradyoxetin appears to upregulate its own synthesis as well as the response regulators *nolA* and *nodD2*, whose products repress the expression of *nod* genes necessary for symbiotic root nodule formation in legumes. This system is yet another instance of quorum signal production being controlled by population density as well as the metabolic state of the organism.

Pseudomonas aeruginosa Pseudomonas Quinolone Signal (PQS)

In addition to the LasI- and RhII-produced AI-1 AHL signals, *P. aeruginosa* synthesizes a quinolone compound PQS important for quorum signaling gene expression. PQS was discovered in 1999 by Everett Pesci, and its chemical structure is 2-heptyl-3-hydroxy-4-quinolone (Figure 5). PQS is synthesized from anthranilate via the *phnAB* and *pqsABCDE* gene products, which produce the precursor 4-hydroxy-2-heptyl-quinoline (HHQ). HHQ is converted into PQS by the PqsH protein.

PQS functions as part of the AI-1-mediated quorum signaling network in *P. aeruginosa*. Activated LasR (bound to 3OC₁₂-HSL) can upregulate *pqsH*, ultimately increasing PQS concentration in a 3OC₁₂-HSL-dependent manner. As PQS concentration increases,

it induces *rhlI* expression in a *rhlR*-dependent manner. PQS negative mutants lack the ability to produce many virulence factors that are also absent in *rhlR* mutants. Thus, PQS serves as a link between the LasI/R and RhlI/R quorum signaling systems (Figure 5).

PQS is also interesting due to its hydrophobic nature. The hydrophobicity of PQS suggests that it would be a poorly diffusible signal in aqueous environments. Recently, it has been discovered by our lab that PQS is transported by outer membrane vesicles. This phenomenon allows PQS to be moved by a water-soluble carrier that may also serve to protect the signal from extracellular degradation by other organisms. Another interesting property of PQS is that its production appears to be restricted to *P. aeruginosa* (at least to this point), while its precursor HHQ is synthesized by many other Gram-negative bacteria, notably *Burkholderia*, *Pseudomonas*, and *Alteromonas* species. HHQ has also been shown to act as a signal in *P. aeruginosa* because of its release and uptake by neighboring cells and subsequent conversion into PQS. Thus, the production of 2-alkyl-4-quinolone compounds by these organisms suggests another class of quorum signaling molecules.

Ralstonia solanacearum 3-Hydroxypalmitic Acid Methyl Ester (3-OH PAME)

R. solanacearum is a Gram-negative plant pathogen that causes wilting in many different plant species. *R. solanacearum* infects plants at the root and over several days enters the xylem where it travels to the aerial portions of the plant. *R. solanacearum* colonizes the xylem and expresses several extracellular and intracellular virulence factors. A primary virulence factor in wilting disease is the production of copious amounts of EPS that physically blocks fluid transport through the xylem of the plant, thereby leading to wilting. This disease is very similar to the previously mentioned Stewart's wilt disease caused by *P. stewartii*.

R. solanacearum virulence factor production is ultimately controlled by the concentration of the quorum signal 3-OH PAME (Figure 8). 3-OH PAME is produced by the PhcB protein and released from the cell. When 3-OH PAME reaches a threshold concentration, it interacts with the sensor kinase PhcS, which then transfers a phosphate group to inactivate the PhcR protein. PhcR inactivation allows the regulator PhcA to activate. PhcA ultimately controls the expression of many virulence genes in *R. solanacearum* as well as a LuxI/R-like signaling system encoded by the *soli/R* genes.

3-OH PAME is significant among quorum signals because it is a volatile compound. Volatility of a quorum signal has positive and negative consequences in that it allows rapid signaling over greater distances than an aqueous signal; however, the signal can also diffuse away from receptive cell populations before a threshold concentration is reached. It is interesting that a volatile signal appears to function sufficiently inside plant tissues, which are highly heterogeneous in terms of fluid and gas density. It is also notable that *R. solanacearum* appears to use multiple quorum signal cascades to regulate virulence gene expression much like *P. aeruginosa*.

Extracellular Effectors of Quorum Signaling Systems

Quorum signals are produced by many diverse bacterial species in many different environments. The ability to utilize signals to direct efficient and timely changes in gene expression almost certainly provides that species with a strong competitive advantage for

Figure 8 Quorum sensing in *Ralstonia solanacearum*. PhcB synthesizes the volatile signal 3-OH PAME. 3-OH PAME interacts with the PhcS sensor kinase to phosphorylate the PhcR regulatory protein. PhcR-phosphate is unable to block activity of the PhcA transcriptional regulator that induces expression of virulence genes as well as the *soli/R*-dependent AHL quorum sensing system.

nutrient acquisition and defense. Likewise, a competitor or host would gain tremendous benefit if it were able to interfere with a pathogen or competitors' quorum-sensing system. The evolutionary 'arms race' between quorum signaling and signal interference by other species could be millions of years old, yet was just recently revealed by researchers.

In 1996, Michael Givskov and Staffan Kjelleberg and colleagues described the production of AHL mimics by the marine seaweed *Delisea pulchra*. *D. pulchra* produces several halogenated furanone molecules that structurally resemble AHL signals. Furanones were shown to inhibit quorum signal-dependent swarming motility of *Serratia liquefaciens* as well as several marine bacteria. AHL reporter systems in *E. coli* as well as *V. harveyi* were shown to be inhibited by exogenous addition of furanones. Further work on *D. pulchra* furanones showed that they disrupt quorum signaling by binding to LuxR-type proteins in a competitive fashion with the native AHL signal. In the case of *D. pulchra*, furanone-dependent quorum inhibition could protect the plant from colonization by pathogenic bacteria that regulate motility, biofilm, or virulence gene expression through quorum-signaling systems.

A similar phenomenon was observed in the unicellular eukaryotic alga *Chlamydomonas reinhardtii*, which also produces quorum signal mimics. *C. reinhardtii* grows in soil and freshwater environments where it likely encounters many bacterial species that utilize quorum signaling. It was shown that *C. reinhardtii* produced at least 12 uncharacterized compounds that stimulated the LasR and CepR regulators in *E. coli* reporter strains. Interestingly, none of the compounds stimulated LuxR or AhvR regulators in similar reporter strains, suggesting that the putative AHL mimics produced by *C. reinhardtii* are receptor-specific. The chemical properties of the *C. reinhardtii*-produced mimics suggest that they are AHL-like in nature, but subsequent characterization of the compounds revealed that they are not known AHLs. Despite their dissimilar structure, *C. reinhardtii* AHL mimics were shown to increase the production of many AHL-controlled genes to levels observed with the native AHL; however, some proteins were found to be downregulated by the AHL mimics. The full impact of these results is still unclear, but demonstrates that *C. reinhardtii* likely has significant effects on bacterial quorum signaling in the natural environment.

Recent research by several groups has identified eubacterial and eukaryotic enzymes that degrade AHLs. There are many incidences of production of these enzymes in bacteria, and it appears that one function may be to degrade the bacteria's own AHL signal in order to downregulate the quorum signal response after its desired effects are achieved. Another function of these enzymes may be to degrade AHLs from competing organisms as a means of interfering with their quorum signaling systems. The observation that some enzymes produced by AHL-synthesizing bacteria cannot degrade their own AHLs, yet degrade those produced by other organisms, supports the idea of competitive interference between species.

In a 2004 *Proceedings of the National Academy of Sciences* paper, Carlene Chun and E. Peter Greenberg demonstrated that human airway epithelial cells were able to degrade the 3OC₁₂-HSL from *P. aeruginosa*. As mentioned previously, *P. aeruginosa* can cause respiratory infections in humans. During the course of infection, airway epithelial cells are likely to come in contact with colonizing *P. aeruginosa*, and the ability of the host to interfere with quorum signaling may be of great importance in preventing infection. Surprisingly, this study showed that the degradation of 3OC₁₂-HSL was contact-dependent and that degradation did not occur in culture supernatants from the airway cells. It was also shown that degradation was specific for 3OC₁₂-HSL, C₁₂-HSL, and C₆-HSL. No degradation of C₄-HSL or 3OC₆-HSL was observed. The AHL degradation phenotype varied widely among cell types tested but seemed to occur most frequently in cell lines that were derived from epithelial cells that are most likely to encounter AHL-producing organisms. These data suggest that humans, and potentially other mammals, have evolved mechanisms to specifically defend against AHL-producing bacteria.

Quorum Signal Interaction with the Host

Eukaryotic hosts utilize both quorum signal-degrading enzymes and mimics to interfere with bacterial quorum signaling. Some organisms produce these substances throughout their life cycle, while others produce them in response to bacterial quorum signals. The ability of eukaryotic organisms to sense and respond to quorum signals is fascinating and further emphasizes the affect that prokaryotes may have on the evolution of eukaryotes and vice versa. We will describe a few representatives from the growing number of cases of eukaryotic responses to bacterially produced quorum signals.

The legume *Medicago truncatula* senses and responds to AHL signals produced by *Sinorhizobium meliloti* and *P. aeruginosa*. Many *M. truncatula* proteins are regulated in a similar manner when exposed to AHLs from either bacterial species; however, some proteins are differentially expressed in response to AHLs from one species compared to the other. This suggests that *M. truncatula* has a conserved response to AHLs but also has the ability to discriminate between AHL signals from these bacteria. AHL signals were found to differentially regulate over 150 proteins in *M. truncatula*, the most notable of which were involved in primary metabolic pathways, stress response, and enzymes used in quorum signal mimic production. At this time, it is unclear how these responses specifically benefit *M. truncatula* or how they affect *S. meliloti* or *P. aeruginosa*, but it is apparent that both organisms stimulate a significant change in behavior of the plant.

In 2006, Elmus Beale and Kendra Rumbaugh demonstrated that the soil nematode *Caenorhabditis elegans* is able to sense AHL signals from bacteria. *C. elegans* was shown to preferentially move toward AHL-producing organisms as opposed to AHL-lacking species. This AHL-dependent chemotaxis is thought to aid *C. elegans* in locating bacteria as a source of food. Another surprising observation was that *C. elegans* would move toward *P. aeruginosa* despite the fact that *P. aeruginosa* kills *C. elegans*. After exposure to *P. aeruginosa*, surviving *C. elegans* would display avoidant behavior toward AHL-producing organisms including nonharmful species. This work provides an elegant example of a eukaryote behavioral response to bacterial quorum signals. Another study by the same lab described the ability of *P. aeruginosa* AHLs to enter and modulate expression in mammalian cells; thus demonstrating

that AHLs are able to cross the host cell membrane and stimulate host gene expression. These changes in gene expression are thought to occur through AHL stimulation of host nuclear hormone receptors. Further work demonstrated that *P. aeruginosa* AHLs can induce inflammation, immunosuppression, and apoptosis in immortalized cells as well as primary cell cultures. Many of these events are hallmarks of tissue exposed to *P. aeruginosa* during infection, but it remains to be determined if the responses seen during infection are actually due to *in vivo* AHL signaling or the myriad of other virulence factors *P. aeruginosa* produces.

Diffusion Sensing, Efficiency Sensing, and the Future of Quorum Signaling Systems

In 2002, Rosemary Redfield at the University of British Columbia proposed that quorum sensing may be a property of what she referred to as diffusion sensing. Before her proposal of this concept, quorum signaling had been widely accepted as a cell density-dependent signal that affected gene expression of a population, with the consequence of directing a population to exhibit behavior that affected the group as a whole. The concept of diffusion sensing proposes that individual bacteria sense autoinducer concentrations and subsequent changes in gene expression direct a response that is intended for the individual cell, not the population as a whole. She proposed that evolutionary selection for quorum sensing behavior was selected for by the benefit given to an individual cell that has the ability to use a signal to gather information on properties of the local environment.

While the concept of diffusion sensing is interesting, it must be considered that any receptor-based system should be induced when ligand concentration exceeds that of the receptors' affinity for it. This condition can be achieved either by increased production of signal, decreased mass transfer rate, or decreased local volume around the cell. In quorum signaling, we ascribe that signal-dependent behavior is due to an increase in population and subsequent increase in signal. In many instances of quorum signaling systems, it may indeed be a product of diffusion sensing by the cell. However, observations of autoinducer-producing organisms in some characterized systems seem to indicate behavioral changes that are more beneficial to a group of cells as opposed to an individual. These changes include density-dependent luminescence as well as conjugation, which serve little purpose when local cell numbers are low.

Hense *et al.* in a 2007 *Nature* review attempted to unify the gap between diffusion and quorum sensing and propose the novel concept of efficiency sensing. Efficiency sensing suggests that cells produce signaling compounds to 'test' the population density, volume, and mass transfer rate of their environment. If signal concentration increases, then induction of energetically expensive, signal-dependent pathways occurs. This hypothesis takes into account that signal concentration can be affected by local concentration of cell density as well as the mass transfer rates and the volume of the local environment. Hense and colleagues propose that efficiency sensing provides a means for individual as well as community advantages of diffusible signals to overlap and provide evidence through mathematical models that indicate that spatial distribution of cells may be more important than density.

It is possible that diffusion sensing behavior in individuals may be the primary means of positive selection for organisms that have quorum signaling systems of either low complexity or are newer aspects in the organism's evolutionary history. Thus as bacteria adapt and evolve, diffusion sensing behavior can be recruited into true quorum signaling behavior and exert a community benefit on a population of cells.

What's Next for Quorum Signaling?

Research in quorum signaling initially uncovered a few specific cases that demonstrated density-dependent signaling and its impact on a single response in the signaling organism. Phenomena such as luminescence and regulation of competence were largely thought to be the single process in the cell directed by a diffusible signal, and much initial research focused on utilization of a specific signal and its interaction with a single receptor or transcriptional regulator to direct regulation of just a few related genes or operons. The discovery of orphan regulators in *P. aeruginosa* and other species and the convergence of multiple types of signals involved in gene expression in *V. harveyi*, *V. cholerae*, *P. aeruginosa*, *R. solanacearum*, and *B. subtilis* (to name a few) demonstrate that many organisms utilize quorum signals in increasingly complex pathways. Further research into orphan regulators and how bacteria integrate multiple quorum signal pathways may reveal an even greater role for quorum signaling in bacteria than was previously considered.

There are ever increasing observations of interspecies quorum signal interactions between bacteria as well as interdomain interactions between bacteria and eukaryotic hosts. These studies demonstrate that prokaryotes and eukaryotes may utilize signals not only as a means to detect signal producers, but as a way to defend against them *in situ*. These adaptations shed light on possible therapeutic strategies for infections caused by quorum signal-producing bacteria. The discovery of quorum signal interference, especially in plants, may be useful in developing new variants of commercial crops that are more resistant to bacterial infections.

A poorly understood aspect of quorum signaling is that some microorganisms utilize quorum signals not only as a strict density-dependent signal but also as a way of monitoring and reporting the nutrient status of the environment. PQS signals in *P. aeruginosa* have been shown to be differentially produced in different environmental concentrations of aromatic amino acids. Also, the types of quorum signals produced by *A. ferrooxidans* vary depending on the substrates available to the organism. These phenomena as well as the production of AI-2 and its dependency on the metabolic status of the cell indicate that quorum signal production may serve functions aside from monitoring cell density.

EDITOR-IN-CHIEF

Thomas (Tom) Schmidt is a microbial physiologist and ecologist who studies diverse microbes and microbial communities. Tom received a PhD from The Ohio State University and conducted postdoctoral research at Scripps Institute of Oceanography and Indiana University. He spent much of his career studying the ecology of microbes in soil that are responsible for the exchange of greenhouse gases with the atmosphere. More recently, he joined the University of Michigan and focused his research on the human microbiome. His joint appointment in the Departments of Internal Medicine and Ecology & Evolutionary Biology reflects his expertise in applying ecological and evolutionary principles to understand the functioning of complex microbial communities.

Tom is a fellow of the American Academy for Microbiology and was director of the Marine Biological Laboratory's Microbial Diversity Course in Woods Hole. Through that course and in his laboratory, he has helped numerous scientists incorporate molecular approaches into traditional strategies for studying the microbial world. He currently teaches a university course that merges his research and teaching goals by engaging students in a coordinated study of the effects of diet on the gut microbiome, and he directs a graduate program that combines laboratory sciences and modeling. Tom was a section editor for previous editions of the *Encyclopedia of Microbiology* and was delighted to assume the role as editor-in-chief to help bring the microbial world to an expanding audience.

EDITORIAL BOARD

Bianca Brahamsha is a research microbiologist at Scripps Institution of Oceanography at the University of California, San Diego. She was a biology and history major at Goucher College, earned her PhD in microbiology at Cornell University, and carried out postdoctoral work in molecular genetics as an American Cancer Society fellow at the University of Chicago. Her research interests have centered on bacterial motility, the genetics and physiology of marine cyanobacteria, and on the interactions between cyanobacteria and their eukaryotic predators.

James (Jim) Brown was born in Atlanta, Georgia, and lived in Dade City (Florida), Bloomington (Indiana), Lima (Peru), and Muncie (Indiana) while growing up. From the beginning, he had an intense interest in nature, including anything found in the woods, rivers, beach or ocean that were always nearby.

Jim attended Ball State University beginning in 1976. A single lecture on microbial diversity in a general microbiology class, followed by the announcement of the discovery of the Archaea (George Fox and Carl Woese, 1977), sparked his lasting interest in microbiology. This led to undergraduate research examining *Beggiatoa* in a sulfur spring in French Lick, Indiana. After receiving his BS in biology in 1980, he joined the graduate program in microbiology at Miami University, where he worked on plant tissue culture mRNAs with Prof. Ronald Treick. After obtaining an MS degree in 1982, he moved to the MCD Biology Program at The Ohio State University to work on the molecular biology of methanogenic Archaea in the Department of Microbiology with Prof. John Reeve. While there, Jim worked on polyadenylation of mRNAs, RNA polymerase, and promoters in Archaea, and received his PhD in 1988. Jim then went to Indiana University for 5 years of postdoctoral work in Prof. Norman Pace's lab on the comparative analysis of the structure of a bacterial ribozyme, RNase P.

In January of 1994, Jim started as an assistant professor in the Department of Microbiology and moved to North Carolina State University. Research in Jim's lab focused on the comparative sequence and biochemical analysis of RNA, and in particular RNase P in Archaea. Students in the Brown lab developed a high-resolution model for the structure of this RNA, how it changed over the diversification of the Archaea, the protein subunits associated with the RNA, and how they contribute to the function of the holoenzyme. Jim developed, teaches, and wrote the textbook for a senior-level undergraduate lab course in microbial diversity. Jim is now Professor Emeritus in the Department of Biological Sciences at NC State University.

Jim has a son and two daughters, and is married to Melanie Lee-Brown, professor of biology and director of Research and Creative Endeavors at Guilford College. For fun, Jim enjoys skin and scuba diving, driving (i.e., working on) his 1968 Lotus Super Seven, and restoring vintage racing bicycles. Jim and Melanie have been renovating an abandoned fishing lodge on North Caicos Island (Turks and Caicos Islands, BWI), which will be reopened soon as a bed and breakfast.

Larry Forney is a university distinguished professor and a member of the American Academy of Microbiology with academic appointments in the Department of Biological Sciences and Bioinformatics and Computational Biology at the University of Idaho. Dr. Forney is an evolutionary ecologist who conducts research on the complex array of factors that influence the function, composition, structure, and temporal dynamics of bacterial communities in a wide array of habitats. In recent years he has largely focused on the community ecology of the human vagina across a woman's lifetime with an eye on understanding how changes in community structure and function affect a woman's risk to bacterial vaginosis, sexually transmitted infections, and pre-term birth, and how host factors shape these communities. His research extends to understanding the mutation-selection processes that govern the occurrence and persistence of genetic diversity of bacterial populations in spatially structured environments such as microbial biofilms and porous media. These studies have shown that spatial structure creates conditions in which mutation frequencies are high and selective sweeps are protracted, which leads to extraordinary within species diversity that increases the resilience of populations to environmental changes.

tions in which mutation frequencies are high and selective sweeps are protracted, which leads to extraordinary within species diversity that increases the resilience of populations to environmental changes.

Robert Haselkorn was the F. L. Pritzker distinguished service professor of molecular genetics and cell biology at the University of Chicago, retiring several years ago. He was an undergraduate at Princeton, a graduate student at Harvard, and a postdoctorate in Cambridge, England. He started his teaching career at Chicago in 1961 in biophysics, extending later to microbiology, biochemistry, and chemistry. His research interests have centered on heterocyst differentiation in nitrogen-fixing cyanobacteria, in bacterial genomics, and in the enzyme acetyl-CoA carboxylase in plants, parasites, and people. He is a member of the National Academy of Sciences, a fellow of the American Academy of Arts and Sciences, and a member of the American Philosophical Society. Among other external activities he was a founder and adviser for 20 years to the International Center for Genetic Engineering and Biotechnology, located in Italy and India. For the past 15 years Haselkorn and his wife Margot have been working on selection and supporting a speaker for the Haselkorn Lecture at the University of Chicago,

an award they have endowed. Many of the Haselkorn Lecturers have been Nobel Prize winners or will be soon.

Jennie C. Hunter-Cevera received her PhD from Rutgers University in 1978 (microbial physiology and biochemistry), an MS in microbial ecology in 1972, and a BS in biology from West Virginia University in 1970. She is the founder of Hunter and Associates, a consulting firm focusing on finding integrative solutions to complex problems involving sustainability in the life sciences arena. From July of 2009 to August 2012, she was the executive vice president of Discovery and Analytical Sciences (DAS), Corporate Development and Government Relations. She has 22 years of experience in the pharmaceutical and biotechnology industries (E. R. Squibb and Sons, Cetus Corporation, GeoBiotics, and Universal Foods). She was the co-founder of The Biotic Network and Blue-Sky Laboratory that contracted with biotechnology and pharmaceutical companies on basic and applied natural product research. Dr. Hunter-Cevera was an

employee for 5 years with the Department of Energy as the head of the Lawrence Berkeley National Laboratory's Center for Environmental Biotechnology. She worked in academia for 10 years as the president of the University of Maryland Biotechnology Institute and 2 years as the Interim Provost of Mount St. Mary's University. She also served as project manager for UC Davis's CIFAR (Center for Industrial Food and Agricultural Research). She has published many papers and chapters, and served as senior editor of the *Journal of Industrial Microbiology and Biotechnology* for 10 years. She is a co-section head of microbiology for Faculty of 1000. She holds 15 patents and specializes in areas of screen design for the discovery of natural compounds in the area of human therapeutics, biodefense, sustainable agriculture, bioremediation, and biocatalysis for industrial processes in the food and clothing industries.

While in Maryland, she served as a member of the Executive Committee for Governor Ehrlich's transition team, his Committee on science, technology, engineering, and maths, and was the Technology Representative for Governor Glendenning on the Southern Governor's Association, and she served on the Technology Economic Development Corporation, TEDCO (Board of Directors for 4 years and was Chair for 2 years). Dr. Hunter-Cevera also served on the Advisory Board for the Maryland Industrial Partnerships, the MDBio's Board of Directors, and the MDBio Foundation for 10 years and on the BioIT Coalition for 5 years. She served as an Entremed Board Member for 10 years and served on the Executive Committee for 2 years. She was a board member for Patients with Power, a software company that designs programs for cancer patients to make the best decisions for their treatments. Jennie also served as acting secretary for Maryland's Higher Education Commission in 2015.

She is a member of several professional societies and has served as president of the Society for Industrial Microbiology, the International Marine Biotechnology Association, and the United States Federation of Culture Collections. Dr. Hunter has served on many national committees and commissions and was Chair of the National Research Council's Committee on Large Scale Production of Biofuels from Algae. She also chaired two other NRC Committees: Standing Committee on DOD's Translational Medicine and the DOE's Genome to Life for Biofuels.

She is the recipient of several awards and honors including Maryland's Top 50 Influential People (2007, 2009) and Maryland's Top 100 Women (2003, 2006, 2009), American Society for Microbiology's Porter Award for distinguished research in microbial systematics and taxonomy, elected as a SIM fellow, a member of the ASM Academy of Microbiology, and an AAAS fellow. She is also a WVU Distinguished Alumni Awardee and Nath lecturer and served as an entrepreneurial coach for the UNC Executive MBA program. She was awarded an Honorary Doctorate from West Virginia University, May 2013, and the Rutgers Cook College Dennis M. Fenton Distinguished Graduate Alumni Award in 2014.

She currently serves on the International Advisory Council for Brazil's Fundação Dom Cabral which is a world-class Brazilian business school that develops strategic thinking skills of executives, entrepreneurs, and public-sector managers. In addition, Jennie served 6 years on the Edison Awards Steering Committee and currently serves on the Edison Awards Advisory Board.

Stanley Maloy is a professor of microbiology and associate vice president for research and innovation at San Diego State University. Stanley's research has focused on bacterial and phage genetics and physiology, evolution of infectious diseases, and development of antimicrobials and vaccines. In addition, he has consulted with large and small companies in multiple sectors, played a role in starting several Biotech companies, and served leadership roles in multiple start-up companies.

Dr. McCormick earned her PhD in microbiology in the topic area of intestinal ecology, and completed postdoctoral training at Harvard Medical School. She remained on the faculty of Harvard Medical School where she was an associate professor of pediatric gastroenterology, and director of research for the Mucosal Immunology and Biology Research Center at Massachusetts General Hospital. In 2008, she joined the University of Massachusetts Medical School where she is professor and vice chair of the Department of Microbiology and Physiological Systems. Dr. McCormick is also the founding executive director of the University of Massachusetts Center for Microbiome Research, which she established in 2014. Dr. McCormick is one of the original pioneers in the field now known as cellular microbiology. Her work provided the first evidence that epithelial cells in response to pathogen contact orchestrate a pro-inflammatory program, which recruits inflammatory cells. Dr. McCormick has since identified new, previously

unidentified and unexpected virulence mechanisms that are key to the inflammatory response, leading to both novel biological principles of host-microbe interactions and therapeutic intervention strategies for the treatment inflammatory bowel disease, and cancer. Her work continues to identify novel ways in which microbes interact with the intestinal epithelium, publishing over 100 original research papers and opinion pieces in this area. Dr. McCormick is an elected fellow of the American Academy of Microbiology, is on the Board of Editors for *Gastroenterology*, and *Gut Microbes*, and serves as a member of four Editorial Review Boards.

Dr. Mobley received his BS degree in biology from Emory University in 1975 and his PhD degree in microbiology and immunology from University of Louisville in 1981. He conducted postdoctoral training in biological chemistry and then bacterial genetics in the Center for Vaccine Development at the University of Maryland School of Medicine. He served on the faculty at the University of Maryland School of Medicine from 1984 until 2004 in the Division of Infectious Diseases (1984–97) and then the Department of Microbiology and Immunology (1997–2004) where he led the graduate program. During that time, he held a joint appointment in the Department of Biochemistry and Molecular Biology and trained graduate students in that program. In 2004, Mobley moved to the University of Michigan to chair the Department of Microbiology and Immunology and was installed as the inaugural Frederick G. Novy Collegiate Professor of Microbiology and Immunology.

Dr. Mobley's research interests focus on the molecular mechanisms of bacterial pathogenesis and on the fundamental basic research that will lay the groundwork for future therapeutics and vaccines. His lab studies virulence mechanisms of uropathogenic *Escherichia coli* and *Proteus mirabilis* that cause uncomplicated and complicated urinary tract infections, respectively, and, in the recent past, *Helicobacter pylori* that causes gastritis and peptic ulcer disease. For *E. coli* and *Proteus mirabilis*, his lab is focused on identifying surface-exposed proteins that are both synthesized by the bacteria during a urinary tract infection and conserved among uropathogenic *E. coli* and *Proteus* strains. Using these conserved antigens, his lab is determining the efficacy of candidate proteins as components of a multivalent subunit vaccine to protect against urinary tract infection.

Dr. Mobley is a fellow of the American Academy of Microbiology and a fellow of the American Association for the Advancement of Science and a member and past president of the Association of Medical School Microbiology & Immunology Chairs. He was the recipient of the inaugural University of Michigan Postdoctoral Association Excellence in Mentorship Award in 2012. He is a member of the editorial review boards of *Infection and Immunity* and *Microbiology Spectrum* and has served as a study section member for the National Institutes of Health. Dr. Mobley was awarded and named a distinguished university professor in 2015. This is the University's most prestigious professorship established to recognize senior faculty with exceptional scholarly achievements, national and international reputations for academic excellence, and superior records of teaching, mentoring, and service.

Dr. Mobley has published 255 peer-reviewed articles which have been cited in the literature over 18,000 times as of June 2019, as well as 49 book chapters and 5 books. He has trained 29 PhD students and 38 postdoctoral fellows, and has delivered 232 invited lectures in 21 countries.

Carlos Pedrós-Alió graduated in biology at the Autonomous University of Barcelona and got his PhD in bacteriology at the University of Wisconsin–Madison. After a postdoctoral stay at the Autonomous University he became an assistant professor of microbiology. He moved to the Marine Sciences Institute (CSIC, Barcelona) in 1989 where he was a research professor since 2000. In 2016 he moved to the National Center for Biotechnology (CSIC, Madrid). Dr. Pedrós-Alió's interest is to understand the ecology of aquatic microorganisms. Around 2005 he started to use genomics as a tool to generate hypotheses that could later be tested experimentally. He also likes to study extreme environments such as hypersaline systems, thermal springs, or polar waters. Another interest is in finding the mechanisms maintaining a large number of rare bacteria in aquatic ecosystems. He is also interested in outreach, relationships between art and science, biology of spirituality, fiction writing, and birding.

PREFACE

As with previous editions of the *Encyclopedia of Microbiology*, the 4th edition takes on the challenge of providing a contemporary overview of microbes—the most abundant and diverse forms of life on Earth. These single-celled organisms were the first life forms to inhabit Earth and they transformed the planet and its atmosphere. They continue to maintain Earth's atmosphere, drive essential processes in terrestrial and aquatic ecosystems, and form intimate relationships with all plants and animals. Microbes can reproduce by doubling every 20 minutes or can remain dormant for many thousands of years. They colonize every known habitat on Earth, accounting for approximately half of the living biomass on our planet. Microbes also cause the most devastating diseases known to humans and are winning the antibiotic war we wage against them. Yet, we cannot live without microbes as symbionts of humans and drivers of Earth's biosphere.

Despite the central roles of microbes, we are only just becoming aware of our limited knowledge of interactions among microbes, other organisms, and the environment. Molecular techniques continue to lead a revolution in our understanding of microbial diversity and function, with the new “big data” sciences of genomics, transcriptomics, proteomics, and metabolomics now being applied to communities of microbes. These techniques provide the ability to identify and study complex communities of microbes in diverse environments including the human gut, forest soil, water-treatment biofilters, and the open ocean.

Given the remarkable physiological and phylogenetic diversity of microbes, their capacity for rapid evolution, and the pivotal role of host-associated and environmental microbiomes, it is difficult, if not impossible, to identify contemporary questions in biology that are not influenced by microbes. It is also increasingly difficult to assemble an encyclopedia that provides comprehensive coverage of the vast universe of microbes. Despite these challenges, we have engaged the expertise of scientists around the globe to provide an exceptional overview of and perspective on the microbial world. This edition of the *Encyclopedia of Microbiology* will help readers develop a framework for understanding microbes and will provide references directing readers to the primary literature that is needed for a more thorough appreciation of specific topics.

We have included a number of articles which provide a historical perspective of microbiology that is focused on disease—one of humanity's earliest acknowledgment of microbes. These help frame more contemporary issues in microbiology that have moved far beyond the relatively small collection of microbes that cause disease. Rather than simply alphabetize topics as in traditional encyclopedias, articles in the 4th edition are also listed under the following themes in a Subject Classification: Historical, Microbial Diversity, Physiology and Genomics, Ecology and Evolution, Pathogenesis and Immunology, and Technological Advances and Applied Microbiology. We hope this helps readers navigate the work more effectively.

On behalf of an insightful and collegial editorial team, I hope that you emerge from your forays into the *Encyclopedia of Microbiology* with some of the awe that we share for the elegance and power of the microbial world.

Thomas M. Schmidt
Editor-in-Chief

INTRODUCTION: MICROBIAL DIVERSITY

It is what we think we know already that often prevents us from learning.

—Claude Bernard

One of the difficult lessons for any professional scientist is that, as much as we know, as good as our tools and questions are, our knowledge is crude and far smaller than we imagined when we were students. Particularly troublesome is that most fundamental aspects of various scientific fields are simply not very well understood. The physicist wonders what, exactly, “time” is, how space is structured, and why the Planck Constant is $6.62607004 \times 10^{-34} \text{ m}^2 \text{ kg/s}$ instead of any other number you might care to choose. Chemists argue about the nature of a covalent bond, or whether or not transition states exist in reality. Biologists are at a loss to describe how life originated, or even what exactly life (in a general sense) actually is. In the most important book of modern times, “On the Origin of Species,” Charles Darwin clearly (but not concisely) deconstructs the idea of the biological “species,” and despite what many of us learned in school, our view of the “species” even for multicellular sexually reproducing creatures remains murky. The modern reader of “On the Origin of Species” might be forgiven for concluding that the reason for this is that it is the actual *biology* of species, and by extension “life,” our origin, etc., rather than our concepts of them, that are fundamentally disordered.

The subject of this section of the Encyclopedia is Microbial Diversity. What does this mean? What is “microbial diversity?”

Let us start with “microbial.” Literally speaking, the term “microbial” means small living things, usually understood to mean life too small to see with the unaided eye. The scientific field of microbiology, however, mostly emerged from our need to solve crucial health dangers created by a tiny fraction of microbes. As a result, “microbiology,” and so “microbes,” refer to Bacteria (and in modern times the Archaea), fungi, a scattering of problematic single-celled or small multicellular eukaryotes, and the physiological systems of the human body that manages our interactions with these creatures. This sells the microbial world very short. For 85% of the history of our planet, life was *entirely* microbial, and it remains *predominantly* microbial. In the words of Stephen J. Gould, “*We live now in the ‘Age of Bacteria.’ Our planet has always been in the ‘Age of Bacteria,’ ever since the first fossils—bacteria, of course—were entombed in rocks more than 3 billion years ago. On any possible, reasonable or fair criterion, bacteria are—and always have been—the dominant forms of life on Earth.*” Another view of this comes from the phylogenetic perspective. If you scrutinize any objective/quantitative “Tree of Life,” based on molecular sequence analysis or any other criterion of choice, you will quickly discover that nonmicrobial life is limited to the tips of a small number of otherwise un-noteworthy branches. Only from our self-centered anthropocentric viewpoint is microbiology distinguishable from biology as a whole.

And what of “diversity?” Living things and their morphology, structure, physiology, ecology, internal mechanisms, behavior, interactions, etc., are far more diverse than most of us have been led to believe. For example, if you think you know how mitosis works, look it up in *Giardia* and be amazed. The notion of what constitutes a “gene” in the kinetoplast of *Trypanosoma* requires you to throw almost everything you think you know about molecular genetics away. Then have a look through the genome of the archaeon *Nanoarchaeum*. These are just the tips of icebergs; these and many more can be found within the chapters that follow. And yet . . . all of this diversity rests over an almost entirely uniform biochemistry that speaks to the shared ancestry of all living things on Earth. How, then, do we assess the “diversity” of living things? Historically, this meant comparing the morphology of different living things; this was the origin of Linnaean taxonomy and, to be fair, is very useful for organisms on the human size scale. More recently molecular phylogenetics has allowed us to more clearly understand how creatures are related, and draw an objective and quantitative graph of these

relationships; the molecular “Tree of Life” is a more useful roadmap of biological diversity. But it is clear that an even more sophisticated view of biological diversity is required, for example to describe how horizontal gene transfer impacts “diversity,” and many of these questions emerge from microbiology. Perhaps the most important fundamental question in microbiology today is “What is a microbial species?” In other words, how do we conceive of a “species” in organisms that do not reproduce sexually? This is not a trivial or parochial question; remember that the concept of biological evolution, and so the foundation of the science of biology, emerged directly from exploration of what a “species” is and how it originates, in plants and animals. But this was over 150 years ago. Broadening our view of microbial diversity, how it is structured and its history and origins, is the key to new and deeper biological insight.

And so, as is usual in science, attempt to answer a simple question that raises many more questions and provides few answers. What *is* microbial diversity? I dunno, but let us have a look. ...

James Brown

INTRODUCTION: PHYSIOLOGY AND GENOMICS

The first two editions of EOM were edited entirely by Dr. Joshua Lederberg. The third edition was also planned largely by Dr. Lederberg, but he died during that phase, in 2008, and was replaced by Dr. Moselio Schaechter, promoted from the ranks of associate editors. Dr. Thomas Schmidt was also an associate editor for that edition and moved up to editor-in-chief for the fourth edition.

The time that has passed from the first to the fourth edition has seen remarkable advances in understanding the variety of microbes. Complete genome sequences were determined for 18 microbes by October 1998 and published in the second edition in 2000. By 2019, a single company had determined the complete annotated genome sequences of several thousands of microbes. Comparative genomics, including the ancillary “omics,” as well as the application of systems biology to reconstruct metabolic networks, have provided new insights into many aspects of microbial physiology and genetics. The advent of cryo EM and of single particle cryo EM has revolutionized how we understand the structure of cells and macromolecules. For this fourth edition, we were guided by the splendid organization of the third and additional areas in which considerable advances have been made. The fourth edition now includes articles describing additional features of microbiology: cryo-electron microscopy, CRISPR/*cas*, and metabolic systems biology, as examples of completely new methods to study microbes, circadian rhythms as an important aspect of the physiology of at least one group of microbes, and new developments in our understanding of the many ways in which bacteria and archaea move. We have also made use of updates of chapters that were included in the third edition.

Bianca Brahamsha
Robert Haselkorn

INTRODUCTION: ECOLOGY AND EVOLUTION

Evolution

Seven articles deal with different aspects of evolution. Two articles analyze the remains of the past evolution of microbes in the fossil record. Three other look at theories, mechanisms, and experimental procedures. Two more examine specific aspects of the evolution of viruses and of a ciliate. Finally, one article bridges ecology and evolution looking at the emerging field of evolutionary ecology of microbes.

Ecology

The ecology section contains a few general articles about what microbial ecology is about, and the particularities of the ecology of viruses and rare microorganisms.

The remaining articles can be placed in two complementary approaches: habitat oriented or process oriented. In the first approach there is a lot of attention devoted to extreme environments. These environments are usually exclusively microbial and show the capacity of microbes to deal with really difficult conditions. Besides, the relative simplicity of such ecosystems allows somewhat easier manipulations than in “normal” ecosystems. Several of the latter are also examined in articles ranging from the deep ocean to plastics. Special attention is given to animal and plant habitats and how microbes interact with their hosts.

The process-oriented approach shows, on the one hand, adaptive traits of microorganisms such as the ability to live in diluted environments or to use chemotaxis to find the optimal conditions. One promising and novel avenue to study adaptations is the analysis of the genomes of uncultured microorganisms. On the other hand, several articles review processes relevant at the ecosystem level, from feeding strategies such as myxotrophy to element cycles such as methane formation and oxidation and, finally, to the use of models in microbial ecology.

We hope this collection of articles provides an overview of the exciting times that microbial ecology is going through, with many new discoveries appearing every few years, and a fascinating and invisible world to be explored.

Carlos Pedrós-Alió
Larry Forney

INTRODUCTION: PATHOGENESIS AND IMMUNOLOGY

This section of the encyclopedia focuses on the relatively narrow slice of all microbes that infect living hosts and how the hosts combat these microbes using innate and adaptive immunity. In addition, we examine how antimicrobial agents including unique metabolites and even bacteriophages have been enlisted to combat these infections. This section takes a broad look at infectious agents ranging from prions, viroids, and satellites to the more traditional etiologic agents like bacteria, viruses, fungi, and selected parasites. Also addressed are epidemiologic and diagnostic techniques used to identify and track the spread of infectious microbes including the most advanced diagnostic methods used by the clinical microbiology laboratory. A closer look at pathogenic mechanisms includes groups of virulence factors such as adhesins, iron acquisition, exotoxins of bacteria and fungi, and bacterial endotoxin (lipopolysaccharide). Strategies adopted by bacteria and fungi to colonize implanted foreign bodies such as catheters are also discussed. Plus, infections of the gastrointestinal tract, lung, oral cavity, and the skin are examined. In addition to pathogenic microbes, some articles examine the protective effect of the microbiome and commensal organisms. With respect to immunity this section also focuses on the interplay of the host immune system with pathogenic microbes covering evasion immune strategies in humoral and cellular immunity as well as innate immunology and the complement immune system.

Beth McCormick
Harry Mobley

INTRODUCTION: TECHNOLOGICAL ADVANCES AND APPLIED MICROBIOLOGY

This section focuses on the development and refinement of the tools commonly used for both basic and applied microbiology. The articles in this section are written by authors who personally have worked on developing and fine-tuning technology for research in microbiology. Many of the products and processes described have multiple uses in a variety of disciplines such as health, the environment, food and agriculture, and industrial biocatalysis. The advances made in sequencing, protein analysis, and bioinformatics have given microbiologists new insights into old problems. These advances have also enabled the rapid identification of microorganisms in studies of biowarfare, infectious disease, and pollution of our water sources. At the same time the integration of mathematics and physics with biology and chemistry has provided instrumentation that enables a greater depth of analysis than ever before. Never in the history of microbiology have so many technological advances been developed and commercialized for use by scientists. Microbiologists today are equipped with improved “tools” within the toolbox to push the boundaries of not only elucidating the relationship of microbes to humans, plants and animals but also moving basic research much faster from the bench to development of new products and processes that benefit society and the planet. The renaissance of applied microbiology powered by technological advances has been both exciting and promising in all fields of study.

Glossary

Acinus A minute terminal lobule in the salivary glands.

Apoptosis A process by which cells undergo a natural programmed cell death or physiological cell death in response to diverse stimuli.

Encephalomyelitis Acute demyelinating disease caused by virus without invoking an immunopathologic mechanism.

Epitopes Structural sites on proteins that bind antibodies and T-cell receptors.

Fixed rabies virus Laboratory strains that grow in tissue culture at a predictable rate, with predictable biological properties, and regularly kill inoculated animals within a predictable period.

Guillain–Barré syndrome An acute inflammatory demyelinating polyradiculoneuropathy that in the majority of cases follows a ‘virus-like’ illness.

Hydrophobia The unique characteristic of rabies involving both severe thirst, accompanied by a desire to drink and at the same time intense fear of water, which is regarded as the most specific manifestation of clinical rabies in humans.

Leptomeninges The two innermost layers of the meninges; cerebrospinal fluid circulates between these innermost layers.

Lyssavirus Rabies virus and variant viruses known as ‘rabies-related’ viruses, which share with rabies virus the unique capability to produce a rabies-like encephalomyelitis.

Negri body Cytoplasmic matrix composed of rabies viral nucleocapsid proteins.

Nodes of Ranvier Tiny gaps formed between myelin sheaths that wrap and insulate axons, which themselves (the gaps) are not insulated allowing them to generate electrical activity and pass nutrients and waste into and out of neurons.

Rhabdoviridae Taxonomic family of rhabdoviruses in the order Mononegavirales that distinguishes itself as identifying with bacillus or ‘rod- or bullet-shaped’ virus particles, including Vesicular Stomatitis virus as the prototypical member of the *Vesiculovirus* genus and Rabies virus as the prototypical member of the *Lyssavirus* genus.

Street rabies virus Virus isolated from natural infection that has not been serially passaged in animals or tissue culture.

Superantigen A class of proteins that bind class II major histocompatibility proteins and stimulate powerful non-specific proliferation of T-cells bearing particular V β sequences as part of their $\alpha\beta$ antigen receptor.

Viropexis Entry of virus particles into cells by engulfment, followed by fusion of membrane-bound vesicles with lysosomes.

Xoplasmic transport Bi-directional (anterograde or retrograde) flow of proteins, particles, and organelles along the length of the neuronal cell’s axon or nerve track to reach intraneuronal destinations.

vRNA	Viral ribonucleic acid or genome RNA
VSV	Vesicular stomatitis virus
WCBV	West Caucasian bat virus

Defining Statement

Rabies is an acute neurologic disease caused by a lyssavirus (of the Rhabdoviridae family) that attacks the central nervous system of all warm-blooded animals and humans and is normally a fatal viral infection. The first written record of the disease dates to twenty-third century BC, and in fourth century BC Plato used the word 'Lyssa' to describe the 'erotic passion' or 'madness' (viciousness) associated with the disease at the time. Outbreaks of rabies in Europe were rare until the Middle Ages, when rabies epizootics occurring in dogs, rabid wolves, and foxes were reported in many countries. By the 1700s, rabies was common throughout Europe, particularly in central Europe, and was beginning to be reported in the New World.

Rabies virus (RABV) is a highly neurotropic virus in infected animals and humans. Virus infection in humans causes alternating symptoms of depression and agitation and almost invariably leads to extreme types of violent behavior and death. Hydrophobia is a unique characteristic of rabies in humans. RABV is transmitted to humans from wild and domestic animals, through bites and deposition of virus-laden saliva. The predominant animal reservoir for RABV continues to be in dogs, which causes a sizable clinical problem for humans, especially in those countries, mainly of Asia and Africa and to a lesser extent in Central and South America, where canine rabies is largely uncontrolled.

Rabies and Rabies-Related Viruses

Rabies virus (RABV) is the prototype virus of the genus *Lyssavirus* in the family Rhabdoviridae. RABV, which is distributed worldwide, is a highly neurotropic virus in infected animals and humans, invariably causing a fatal encephalomyelitis, commonly referred to as rabies. Until 1956, RABV was considered the only virus associated with the oldest known disease, recognized in ancient times (as early as the twenty-third century BC) as 'mad dog' disease. Variants of RABV, known as 'rabies-related' or non-RABV lyssaviruses, have since been identified after the initial discovery of two rabies-related viruses originating from Africa: Lagos bat virus (LBV) and Mokola virus (MOKV) in 1956 and 1968, respectively. Rabies-related viruses share with RABV the unique ability to elicit the clinical disease of rabies, producing a rabies-like encephalomyelitis, and also share other RABV structural characteristics. There are now fourteen recognized lyssaviruses, 12 of these have been differentiated into three phylogroups based on phylogenetic analyses. RABV (formerly identified as genotype 1) belongs to phylogroup I along with Duvenhage virus (DUVV) (genotype 4), European bat lyssavirus, type 1 (EBLV-1) (genotype 5), and type 2 (EBLV-2) (genotype 6), and Australian bat lyssavirus (ABLV) (genotype 7). Three putative species, Aravan virus (ARAV), Khujand virus (KHUV), Irkut virus (IRKV), and Bokeloh bat lyssavirus (BBLV) the newest of species to be characterized are considered independent species of phylogroup I. Phylogroup II includes LBV (genotype 2), MOKV (genotype 3), and Shimoni bat virus (SHIBV), the newest of species to be characterized and considered an independent species within phylogroup II. West Caucasian bat virus (WCBV) and the Ikoma lyssavirus (IKOV), isolated from an African civet, which do not cross-react serologically with any members of the two phylogroups, could tentatively belong to a third phylogroup (phylogroup III). Phylogenetic analyses suggest that all lyssaviruses originate from a precursor bat virus.

Virus Structure

RABV and the non-RABV lyssaviruses belong to the class of RNA viruses that contain a linear, single-strand, negative-sense (noninfectious) RNA genome that is approximately 12 kb or 12 000 nucleotides (nts) in length ($M_r 4.2 \times 10^6$). The viral genome (2–3% of the virion weight) forms the backbone of the tightly coiled helical RNP (ribonucleoprotein/RNA plus protein) core, which extends along the longitudinal axis of the bullet-shaped virus particle (Figure 1). The RNA genome contains five genes that code for the five structural proteins of the virion, which are designated N (nucleoprotein), P (phosphoprotein), M (matrix protein), G (glycoprotein), and L (RNA transcriptase/polymerase or large protein). The five genes are organized in the genome in order, starting at the 3' end, N, P, M, G, and L. The first four genes are separated by short (di- or penta-) intergenic nt stretches (N–P, P–M, and M–G) and a longer 19–28-nt sequence between the last L gene and the G gene (Figure 2). The full nucleotide sequence of the RNA genome includes a noncoding leader (Le) sequence at the 3' terminus and a noncoding trailer (Tr) sequence at the 5' end. These short (58–70 nt) sequences provide specific *cis*-acting signals (a specific nucleotide sequence 'acting within' the genome RNA) to initiate specific functions in genome RNA transcription and replication.

Figure 1 Schematic representation of the rabies virion. The drawing shows the internal ribonucleoprotein (RNP) core consisting of the single-strand, negative-sense genome RNA encapsidated with nucleocapsid protein (N), the virion-associated RNA polymerase (L), and polymerase cofactor phosphoprotein (P). The RNP core in association with the matrix protein (M) is condensed into the typical bullet-shaped particle that is characteristic of rhabdoviruses. A lipid bilayer envelope (or membrane) in which the surface trimeric glycoprotein (G) spikes are anchored surrounds the RNP-M structure. The membrane 'tail' depicted in the drawing represents the trailing piece of envelope that is frequently observed attached to the virus as it buds from the plasma membrane of the infected cell when viewed under the electron microscope (EM). Reproduced from Wunner, W. H., Larson, J. K., Dietzschold, B., Smith, C. L. (1988). The molecular biology of rabies viruses. *Review of Infectious Diseases* 10(Suppl. 4): S771–S784, with permission.

Figure 2 Organization of the rabies virus (RABV) RNA genome. The nucleoprotein (N), phosphoprotein (P), matrix protein (M), glycoprotein (G), and large RNA-polymerase protein (L) genes (orange) are separated by four intergenic nucleotide sequences and flanked by the leader (Le) RNA and trailer (Tr) RNA sequences (green) at the 3' and 5' termini, respectively. Numbers shown above the five genes and below represent nucleotides per gene and in the Le, Tr, and intergenic nucleotide sequences, of the RABV Evelyn–Robitnicki–Abelseth (ERA) strain. Reproduced with modification from Wunner, W. H. (2007). Rabies virus. In: Jackson, A. C., Wunner, W. H. (eds.) *Rabies*, 2nd edn., pp. 23–68. San Diego, CA: Elsevier, Academic Press; From Wunner and Conzelmann (2013) Rabies virus. In: Jackson, A.C. (ed.) *Rabies*, 3rd edn., pp. 17–60. San Diego, CA: Elsevier, Academic Press, with permission.

The five structural proteins of RABV (as well as non-RABV lyssaviruses) comprise 67–74% of the virion by weight. The three viral proteins associated with the viral RNP core include the N (the most abundant protein in the RNP core) and the noncatalytic polymerase-associated P and the catalytic L components of the RNA polymerase complex. All three proteins are involved in the RNA polymerase activity of the virion, which generates monocistronic mRNA transcripts of each of the viral protein genes and a full-length complementary (plus-sense) transcript of the viral genome that serves as a template to produce a progeny (negative-sense) RNA genome. The remaining two structural proteins of RABV, G and M, are associated with the lipid bilayer envelope that surrounds the RNP core. M is a small-size nonglycosylated protein that lines the viral envelope forming an inner leaflet between the envelope and the RNP core. G is the only glycoprotein. It forms the trimeric spikes on the outer surface of the viral envelope. The mature viral G is glycosylated with branched-chain oligosaccharides, which account for 10–12% of the total mass of the protein. There are approximately 450 trimeric spikes distributed on the outer surface of each virion. Other host-derived minor protein components such as actin and heat shock proteins of the hsp70 type, CD44 and CD99-related glycoprotein (VAP21), are also found in rabies virions. The role of these proteins is unclear; it is possible that some of them act to chaperone the viral proteins during synthesis and are incorporated into virions after binding to and assisting in G folding. Cytoskeletal proteins normally expressed on the host cell surface may also be incorporated into virions as a consequence of their proximal location and function in virus budding. Some of these proteins ensure intracellular transport of viral RNP along the pathogenetic pathway of the virus. A lipoprotein bilayer that forms the viral envelope around the helical RNP core is therefore a mixture of viral and host proteins and lipids, which constitute 20–26% of the viral envelope.

RABV particles or virions are best described as bacilliform or bullet-shaped with one end rounded (hemispherical) and the other end flattened (planar) (see [Figure 1](#)). The physical appearance of this rigid rod-like, bullet-shaped virion was first described from images seen using the electron microscope (EM). The average length of standard-size, infectious virions is 180 nm (130–250 nm) and the average diameter is 75 nm (60–110 nm). Besides standard-size virions, other shorter, often cone-shaped virions are sometimes observed. These are defective virions that have genomes approximately one-third to one-half the size of the full-length genome of standard-size virions. These shorter genomes are the result of internal nucleotide sequence deletions that occur during virus replication, particularly in virus-infected cell cultures.

Viral Protein Function

The nucleoprotein (N; 450 amino acids) is the most abundant of the viral proteins produced in RABV-infected cells. The model for rhabdovirus genome transcription proposes that the viral RNA polymerase will produce the greatest number of transcripts (mRNA copies of a gene) from the gene closest to the 3' end of the RNA genome. A gene that is closer to the 3' end of the genome is transcribed more frequently than the next gene and so on along the genome. One of the primary functions of N is to 'encapsidate' the nascent (newly synthesized) viral RNA that is made during virus replication, which protects it from ribonucleases that degrade naked single-stranded RNA in the cell. The most conserved amino acids of N stabilize certain key protein-RNA interactions. N is also the major protein of cytoplasmic inclusion bodies (Negri bodies) that are prominent as morphologically distinct lesions found in infected neurons of the diseased brain ('rabies pathogenesis and histopathology'). Although the amino acid sequence of N is the most conserved of the viral proteins among the lyssaviruses, the noted amino acid differences provide unique, genotype-specific epitopes on the N making it a useful protein for comparative antigenic analysis and genetic typing based on its nucleotide sequence in diagnostic and phylogenetic analyses. Determination of a stretch of nucleotide sequence is a commonly applied method for comparing a collection of lyssaviruses and allowing by sequence alignment a direct comparison of virus isolates to reference sequences leading to the phylogenetic classification of a particular virus.

N is the second most extensively analyzed of the RABV proteins (after G) with respect to its antigenic and immunogenic structure and function. The RNP of RABV induces protective immunity against peripheral challenge, with lethal RABV (infection by a virulent form of RABV) in animals due to dominant B- and T-cell-specific epitopes (amino acid regions) on N. Three antigenic epitopes (antibody binding sites) on N have been mapped to amino acids 358–367 (antigenic site I) and three linear epitopes (antigenic site IV) have been mapped to two independent regions, amino acids 359–366 and 375–385. The apparent paradox that N appears to have two independent antigenic sites (I and IV) recognized by antibodies that do not compete with each other for binding to the N antigen suggests that the two overlapping epitopes are recognized independently on different forms of N. The paradox was resolved when it was discovered that N, which is diffusely distributed in the cytoplasm and available to encapsidate RNA, represents one form and the N that is associated with cytoplasmic inclusion bodies represents the other form. N is also the major target for T-helper (Th) cells that cross-react among rabies and rabies-related lyssaviruses. N has other properties that enable it to function as an exogenous viral 'superantigen', and is perhaps the only viral superantigen that has been identified in humans. Some of the properties include its potent activation of peripheral blood lymphocytes in vaccinated humans and its ability to produce a more rapid and heightened virus-neutralizing antibody (VNA) response upon injection of inactivated rabies vaccines. N is also capable of inducing early T-cell activation steps and expansion and mobilization of CD4⁺ Vβ8T-cells to trigger and support production of VNA and bind to HLA class II antigens expressed on the surface of cells.

Phosphoprotein (P; 297 amino acids), which is derived from the second gene (next after the N gene) in the RABV and non-RABV lyssavirus genome, is a multifunctional protein and a key component and regulatory protein of the virion-associated RNA polymerase complex in viral genome replication. In the cell, one of the functions of P is to act as a chaperone specifically directing N to encapsidate viral RNA, by interacting with newly synthesized (nascent) soluble N (N^o) to maintain N^o in a competent form for RNA encapsidation, preventing N^o from polymerizing (self-aggregating) and nonspecifically binding to cellular RNA. P also plays a pivotal role as a noncatalytic cofactor in the transcription and replication of the viral genome. It serves to stabilize L and place the polymerase complex on the RNA template, which L alone is unable to do. These two functions of P are accomplished via domains of P that are specific for each of these two proteins. P is present in the infected cell in a form that is distinguishable from its presence in the virion and these forms can be differentiated by their degree of hypo- to hyperphosphorylation when resolved by electrophoresis in sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE). Phosphate groups are added to RABV P by two distinct protein kinases, one of which phosphorylates the protein at serine (S)63 and S64 in the N-terminal portion of the molecule altering the migration of P in SDS-PAGE. The other kinase, which appears to be selectively packaged in mature virions, does not alter the migration of P in SDS-PAGE. Other protein-protein interactions that involve RABV P are equally important, such as its interaction with cellular proteins that influence or help regulate virus tropism and cell-to-cell spread. Dynein light chain 8 (LC8) is a cellular protein, part of cytoplasmic dynein and the myosin V microtubule-associated motor protein complex that facilitates the transport of RABV through neurons. Other interactions include the inhibition of innate immune responses, such as the interferon (IFN) response, that typically prohibit productive virus replication.

The rabies virion-associated RNA polymerase or large protein (L; 2142 amino acids) is the catalytic component of the polymerase complex of RABV. It is encoded in the fifth or most distal gene from the 3' end of the RNA genome, which accounts for more than half, 54%, of the viral genome-coding potential. Along with noncatalytic P, L is responsible for the majority of enzymatic activities involved in viral RNA transcription and replication. The virion-associated RNA polymerase has the unique function at the start of infection to initiate the primary transcription of the genome RNA after the RNP core is released into the

cytoplasm of the infected cell. The transcripts, which include the 3' Le RNA and monocistronic mRNAs of the N, P, M, G, and L genes, are initiated, elongated, and in the case of mRNAs cotranscriptionally modified to include 5' capping, methylation, and 3' polyadenylation. These enzymatic activities that are assigned to L are identified with but not precisely mapped within one (block III) of four blocks of highly conserved amino acid sequences distributed noncontiguously in L. Block III, the catalytic domain, between amino acid residues 530 and 1177 in the central part of the primary sequence of L, consists of four motifs (A–D) that represent regions of highest similarity and are thought to constitute the polymerase module of L. These structurally conserved motifs are engaged in the transcriptional activity of L that requires binding of substrate ribonucleoside triphosphates (rNTPs), polyadenylation, and protein kinase activity for specific phosphorylation of the P in transcriptional activation. At least two other consensus sequences bind ATP that is utilized in the essential activities of L.

The matrix protein (M; 202 amino acids) of RABV and the non-RABV lyssaviruses is derived from the third gene in the RNA genome. It is the smallest of the virion proteins. There are two isoforms of M: a major form, M α , which accounts for 70–75% of total M in lyssa virions, and a minor form, M β , which accounts for the rest of M in the virion, but only 10–15% of total M in the cell. M plays a critical role in the morphogenesis of lyssa virions as it binds to and condenses the nascent RNP complex (nascent virus core) into a tightly coiled, helical RNP-M structure, forming a sheath around the RNP core. This structure, which assumes a 'bullet' shape, is referred to as the virus 'skeleton.' At the time that M binds to the RNP core, it also interacts with the host plasma membrane at the marginal region of the cytoplasm where it initiates the virus budding process from the plasma membrane. The virus budding process appears to be triggered by a proline-rich motif (PPEY), referred to as a 'late-budding domain' (L-domain), located within the highly conserved 14-amino acid sequence near the N-terminus of the RABV M. Similar proline-rich motifs identified in other types of budding viruses are also associated with virus budding from the plasma membrane. While the release of virus particles from the plasma membrane of infected cells requires the M of the RNP-M skeleton structure, the efficiency of virus budding is greatly enhanced by the interaction of the skeleton structure with the viral envelope glycoprotein (G).

The glycoprotein (G; 505 amino acids) of RABV, like non-RABV lyssaviruses, is translated from mRNA that is transcribed from the fourth gene in the RNA genome. The G gene encodes a 524-amino acid protein, which includes a signal peptide of 24 amino acids at the N-terminus that is posttranslationally cleaved before the mature 505-amino acid G is integrated into the envelope of the virion. G is a type I glycoprotein, which indicates that the protein is anchored in the membrane envelope by a transmembrane (TM) domain located near the C-terminus of the protein. The short C-terminal portion (22 amino acids) of G that remains beneath the membrane (toward the cytoplasm) is the cytoplasmic domain (CD) and the large N-terminal portion (439 amino acids) of the mature G, the ectodomain (ED), extends outward from the membrane surface of the infected cell and released virion. The CD of G interacts with M of the skeleton particle to complete virion assembly and enables efficient release of virions. During posttranslational modification (glycosylation) of G in the endoplasmic reticulum (ER) and Golgi apparatus, three molecules of G form trimers (aggregates of nascent G molecules presumably held together at the TM domain), which later become the trimeric spikes on the surface of the virus. The ED of each molecule in the trimeric spike is responsible for virus binding to cell surface receptors and the entry of virus into cells in the early phase of the RABV life cycle and for induction of anti-rabies VNA, when engaging the host's defense against the virus.

Glycosylation of RABV G is important for its expression on the membrane surface and proper function. Complex carbohydrates (oligosaccharides) are linked to asparagine residues in the tripeptide sequence (sequon) asparagine-X-serine or asparagine-X-threonine, where X is any amino acid except proline. While RABV G can have one, two, or three (or sometimes four) sequons (N-glycan sites) per molecule, not all sites are occupied on all molecules, which depends on various factors that influence efficiency of glycosylation. At least one site (N319 in RABV G) is required, however, and it is a sequon that is highly conserved in all the lyssavirus genotypes and other rhabdoviruses such as vesicular stomatitis virus (VSV). The sugar residues of N-glycan are pre-synthesized in the cell and transferred from a lipid precursor by the enzyme oligosaccharyltransferase as a precursor core oligosaccharide unit (Glc3Man9GlcNAc2) to the specific sequons of the nascent G molecule, as the protein is processed in the lumen of the ER and Golgi apparatus. There the high-mannose core oligosaccharide unit is trimmed with the help of the chaperone calnexin, which assists in the correct folding of G to achieve its biological activity, stability, and antigenicity.

A key biological role of G is its ability to facilitate virus entry into host cells after targeting the binding of the virus to its receptor(s) on host cells. Acting as a fusion protein, the lyssavirus G enables the virus to become internalized as it triggers a low pH-dependent fusion with the plasma membrane and endosomal membranes to enter cellular endosomes. During this process, G assumes at least three structurally distinct 'conformational' states. The G on the virion surface assumes the 'native' state prior to the virus binding to the cellular receptor. After the virus attaches to the receptor and is internalized, the G on the virion surface is 'activated' to a hydrophobic state, enabling it to interact with the hydrophobic endosomal membrane. After entering the endosomal compartment and its low-pH environment, the fusion capacity of G is further activated via a major conformational change in the G that exposes the fusion domain, which interacts with and destabilizes one or both of the participating membranes. Once activated to fuse with endosomal vesicles, the viral uncoating process begins; at pH 6.2–6.3, G assumes a reversible 'fusion-inactive' conformation, which makes the G monomer appear longer than the 'native' form and assume selective antigenic distinctions and be highly sensitive to cellular proteases. RABV spreads from cell to cell in two ways. It either buds from one infected cell into the culture medium (*in vitro*) or extracellular space (*in vivo*) to infect another cell by attaching to the next cell's surface receptor or spreads directly from cell to cell without budding into the culture medium or extracellular space. The precise method of direct cell-to-cell spread of virus *in vitro* and *in vivo* has not been determined. But the fact that the virus can enter a cell without first attaching to the cell surface receptor in cell culture (direct cell-to-cell spread) points to the importance of the pH-dependent and pH-independent fusion functions of G in virus spread.

Another important biological role of G is its ability to define the pathogenicity of the virus and determine the neuroinvasive pathway the virus takes to reach the central nervous system (CNS) and the brain, and cause a lethal infection. The RABV and non-RABV lyssavirus strains are defined by their 'neurotropism' as having a pathogenic (virulent) or nonpathogenic (avirulent) phenotype. The virulent virus causes a lethal infection, while the avirulent virus does not cause a lethal disease. The virulent and avirulent phenotypes are often defined by a single amino acid substitution in G. The position most often associated with a single amino acid substitution causing the change from virulent to avirulent phenotype is the position 333 of the 505-amino acid sequence. Normally, arginine occupies position 333 in the G of the virulent phenotype, while glutamine or lysine occupies the same position in the G of the avirulent phenotype. Although substitution of other amino acids at position 333 can make this transition in phenotype happen, there are still other identifiable factors that can play a role in the pathogenicity of RABV and non-RABV lyssaviruses. These may include the transcription activity of L, the length of the long intergenic nucleotide sequence between the protein-coding or open reading frame (ORF) regions of the G and L genes, and optimal protein-protein (e.g., G-M) interactions. Nevertheless, at least with 'fixed' strains of pathogenic and avirulent RABVs that distinguish themselves by having an arginine and glutamine at position 333 of their G, respectively, all else being the same, it has been shown that the two phenotypes invade the CNS from a peripheral site at different rates. It is clear that not only does the G allow entry into the nervous system by selecting the appropriate receptor it facilitates and enhances retrograde axonal transport of the virus to the CNS. By selecting different neuronal pathways to the brain from a peripheral site of inoculation, it is also clear that the pathogenic virus reaches the brain faster than the avirulent phenotype. Still, other studies have found that the two virus phenotypes showed no difference in the rate of speed and pathway of spread to the CNS. So, it remains controversial and requires further investigation into whether the viruses, depending on their amino acid constituents in the G and phenotype, use different receptor sites on the cell surface or use the same receptor sites with different efficiencies in determining the neuronal pathways for the viruses.

Finally, RABV G is highly immunogenic and of major importance for the induction of VNA and T-cell-mediated immunity, two of the host's adaptive immune responses against virus infection. G induces VNAs that recognize both conformational and linear antigenic epitopes and stimulates helper as well as cytotoxic T-cell activity. The various epitopes that bind VNAs delineate a total of eight antigenic sites that have been physically mapped (located) on the ED of G. Epitopes that bind T-cells have also been mapped on G. To visualize and understand the precise topography of the antibody and T-cell binding sites on the G, it will be necessary to study the three-dimensional structure of the antigen (derived from G crystals). So far, this has denied investigators, who have made numerous attempts to crystallize the RABV G for X-ray diffraction analysis, any success.

Viral Genome Structure

The linear single-strand negative-sense RNA (vRNA) of lyssavirus genomes of about 12 kb in length includes the 5 genes that appear in a strictly conserved order 3'-N-P-M-G-L-5' flanked by the short 3'- and 5'- terminal regulatory extragenic regions known as leader (Le) and trailer (Tr) regions. These two extragenic regions are terminated by unmodified 3'-hydroxyl (3'-OH) and 5'-triphosphate (5'-PPP) ends, respectively (Figure 2). The Le region, acting as a genetic promoter (GP), initiates transcription of five monocistronic mRNAs from the genes of the vRNA genome as well as the synthesis of full-length antigenome RNA (cRNA). The 3'-end of the cRNA functions as the antigenome promoter (AGP) that directs synthesis of full-length N-encapsidated vRNAs representing synthesis of progeny vRNAs in viral genome replication. Much as recently been learned from X-ray diffraction studies of crystal ring structures of helical N-viral RNA (N-vRNA) or RNP complexes containing as few as 10 N molecules how the genome vRNA is encapsidated by N. One should not lose sight of the role that P plays in directing N encapsidation of vRNA (see description of P above) and that an N-P complex is involved in vRNA encapsidation process. The vRNA in these structures is sequestered in a cavity at the interface between the N- and C-terminal lobes of N that seem to 'clamp down' onto the bound RNA. The complete occlusion of the vRNA by N (N-vRNA) explains the excellent protection of the vRNA against high salt, attack by RNases, and silencing by siRNAs. During transcription and replication of the viral genome RNA, the tight clamping of the N-vRNA interaction opens exclusively and transiently to allow the polymerase complex access to the vRNA. Easiest access to the N-vRNA genome would be at the 3'-end of the genome as well as the 3'-end of the antigenome (N-cRNA) to allow transcription and replication of the downstream copying of successive genes to occur.

Gene Transcription and Genome Replication

The Le RNA and mRNAs of the five genes are sequentially transcribed off the N-vRNA genome according to the widely accepted stop/start model of transcription for all single-strand (non-segmented) negative-sense RNA viruses. The first transcript initiated by the 3'-terminal GP is the Le RNA, however recent studies suggest that transcription of the downstream protein-encoding genes starting with the N gene can proceed independent of Le RNA synthesis. Directing the activity of the viral RNA polymerase, acting as a transcriptase, are conserved stop/start signals separated by non-transcribed intergenic sequences at the gene borders that control the observed transcription. A short run of mostly 7 U residues signal the polymerase to stop transcription while the polymerase continues to move back and forth on the N-vRNA template to synthesize a 50–150 nt-long poly(A) tail that is added onto the mRNA. Without fully separating but purposely dissociating from the N-vRNA template at the gene borders, it is thought that the polymerase releases the newly synthesized polyadenylated mRNA and re-associates with the template to initiate transcription of the next downstream gene at the restart signal without transcribing the border signals between sequential genes. Since the polymerase enters exclusively at the 3'-end of the genome and dissociates from the genome at every gene junction, upstream mRNAs are produced more abundantly than

downstream mRNAs. This stop/restart process of the polymerase as it travels along the genome represents an efficient method of attenuation of transcription creating a differential accumulation of transcription products for translation. The mRNAs typically have a 5'-terminal 7-methylguanylate cap structure (m⁷G) for translation initiation and a short 5'-noncoding region of 20–30 nts, as well as a longer 3'-noncoding region of 100–500 nts prior to the poly(A) tail. A particularly long 3'-noncoding region exists in the RABV G mRNA corresponding to the long intergenic region in the RABV genome between the G and L genes (initially described as a pseudogene). Differences in the 3'-noncoding region of genes mostly account for the differences in the overall length of lyssavirus genomes. The mRNAs produced are efficiently translated by host cell protein synthesis machinery into the viral proteins. Replication of the negative-sense (-strand) genome requires synthesis of the full-length positive-sense (-strand) antigenome (cRNA) or replicative intermediate. The cRNA is produced by the viral polymerase, acting as a replicase ignoring the stop/start signals that delineate the mRNAs. Synthesis of the cRNA starts at the 3'-end of the N-vRNA by primer-independent synthesis to produce the 5'-end of the cRNA antigenome (complementary to the vRNA) including a sequence corresponding to that of the short leader RNA. Like the N-vRNA, the newly formed positive-strand cRNA is encapsidated by N (N-cRNA) as the cRNA sequence is elongated in the 5–3' direction. The resulting antigenome cRNA by definition has a 3'-end that is identical in the first 11 nts to that of the genome vRNA and can efficiently direct the synthesis of abundant amounts of progeny genome N-vRNAs from the N-cRNA template. Since progeny genome vRNAs makes up 98% of full-length RNAs in virus-infected cells, it is obvious that the AGP is much more active in directing genome replication than GP is in directing full-length genome transcription.

Virus Life Cycle

Following the bite of a rabid animal, infectious virus in the saliva is introduced into the bite wound and enters susceptible cells in the muscle or skin at the wound site and the virus's life cycle begins. In the virus-infected cell the virus begins to multiply (replicate) to produce more (progeny) virus. RABV and non-RABV lyssaviruses maintain their life cycles in selected (targeted) cells of the infected host. After the virus enters the first cell and replicates, the progeny virions bud from the cell and spread to other susceptible cells. As more progeny virions are produced, more and more (the growth can be exponential) infectious particles populate the extracellular space (*in vivo*) or enter the medium of cell culture (*in vitro*). Typically, RABV does not enter or circulate in blood. The sequence of events in the RABV life cycle can be divided into three phases. In the first, or early phase, the virus particle either attaches to the surface of a targeted or susceptible host cell via a cell surface receptor or enters the cell via direct virus fusion (externally) with the plasma membrane through coated pits (viropexis) and subsequently (internally) with endosomal membranes of the cell. During the endosomal fusion process (called endocytosis), virus particles are stripped (uncoated) of their viral envelope components and the helical RNP is released into the cytoplasm. When the virus attaches to the surface of a target cell via a 'specific receptor,' it most likely binds to a receptor molecule or cellular receptor unit (CRU) that leads to or permits direct virus entry into the cell. Various 'receptor' molecules have been implicated in binding RABV to cells in culture including lipid, gangliosides, carbohydrates, and proteins of the plasma membrane, but none have been proven to be 'specific' receptors. However, three specific *in vivo* CRUs appear to correlate with the defined neurotropism of the virus. The nicotinic acetylcholine receptor (nAChR), the first identified receptor for RABV found at neuromuscular junctions, where RABV can also be found colocalized *in situ*, is regarded as a likely candidate for a receptor for the virus. It was thought that RABV binding to AChRs would localize and concentrate the virus on post-synaptic cells at neuromuscular junctions facilitating uptake and transfer of virus to peripheral neurons and ultimately the CNS. Another possibility is the neural cell adhesion molecule (NCAM) CD56, a cell adhesion glycoprotein, which is found on the cell surface of RABV-susceptible cell lines (*in vitro*) as well as *in vivo*. Blocking the NCAM receptor with the physiological inhibitor heparin sulfate or specific anti-NCAM receptor polyclonal or monoclonal antibodies, which inhibited RABV infection of susceptible cells expressing NCAM receptor helped identify this receptor molecule as a cell surface receptor for RABV. A third possibility is the low-affinity p75 neurotrophin receptor (p75NTR), a nerve growth factor receptor expressed on the surface of cultured BSR cells. Whether p75NTR is an obligatory receptor for RABV has been questioned since the challenge virus standard (CVS), a fixed laboratory strain of RABV infects mice that lack p75NTR. Whatever receptor is present on the cell surface *in vivo*, it seems the virus is not limited to choosing only one type of receptor in order to initiate the virus life cycle in the infected animal or human.

In the second or middle phase of the RABV life cycle, after the virus is internalized by endocytosis in the cell, the tightly coiled transcriptionally 'frozen' viral RNP core, which is released into the cytoplasm, relaxes to form a loosely coiled RNP helix to facilitate N-vRNA genome transcription and replication in the cytoplasm. The viral proteins are synthesized from the viral mRNA transcripts. Four of the mRNAs, N-, P-, M-, and L-mRNA, are translated on free ribosomes in the cytoplasm and the G-mRNA is translated on ribosomes bound to the ER (referred to as the rough ER). Before the nascent G is completely synthesized, it enters cotranslationally into the lumen of the ER where the protein is folded with the help of molecular chaperones and undergoes modification at the asparagine-X-serine or -threonine sequons by core glycosylation and N-glycan processing, that is, trimming of high-mannose triglycosylated oligosaccharides in the rough ER and Golgi stacks to form the 'complex type' N-linked monoglucosylated oligosaccharide of the mature G molecule. After final processing of the N-linked carbohydrate side chains in the Golgi apparatus, viral G trimers are formed and appear on the plasma membrane surface of the infected cell. While protein synthesis is happening, the incoming genome vRNA is transcribed into full-length positive-strand cRNA (antigenome RNA or replicative intermediate), which in turn is copied into full-length negative-strand progeny genome RNA or vRNA (Figure 3).

In the late phase of the RABV life cycle, once sufficient pools of vRNA and viral N, P, and L proteins have accumulated, vRNA is encapsidated by N (directed by the N-P complex) and L is added and nascent rabies viral RNP complexes are formed. 'Skeletons' of

Figure 3 Rabies virus (RABV) life cycle in the cell. Virus enters the cell following attachment through coated pits (virophexis) or via cell surface receptors, mediated by the viral glycoprotein (G) fusing with the cellular membrane (endocytosis). After internalization, the viral G mediates low pH-dependent fusion with the endosomal membrane and the virus is uncoated, releasing the helical nucleocapsid (NC or N-vRNA) of the ribonucleoprotein (RNP) core. The five structural genes (N, P, M, G, and L) of the genome RNA (vRNA) in the NC are transcribed into five positive (+) strand monocistronic messenger RNAs and a full-length (+) strand (antigenome) cRNA (replicative intermediate). The antigenome cRNA serves as the template for replication of progeny genome (-) strand vRNA. The proteins N, P, M, and L are synthesized from their respective mRNAs on the free ribosomes in the cytoplasm and G is synthesized from the G-mRNA on ribosomes bound to endoplasmic reticulum (rough ER). Some of the N-P molecular complexes produce cytoplasmic inclusion bodies (Negri bodies) *in vivo* and some N-P complexes encapsidate the (+) strand and (-) strand viral RNAs. After progeny genome RNA is encapsidated by the N-P protein complex, and L protein is incorporated to form progeny RNP (both full-length standard and shorter defective) structures, the M protein binds to the RNP and condenses the RNP into the 'skeleton' structures. The skeleton structures interact with the trimeric G protein structures anchored in the plasma membrane and assemble into virus particles that bud from the plasma membrane of the infected cell into adjacent extracellular or interstitial space. Reproduced from Wunner, W. H. (2007) Rabies virus. In: Jackson, A. C., Wunner, W. H. (eds.) *Rabies*, 2nd edn., pp. 23–68. San Diego, CA: Elsevier, Academic Press, with permission.

virus particles and finally mature virus particles are assembled with the addition of M and G, respectively, to the RNP complexes. During RABV morphogenesis, an amorphous, intracytoplasmic ground substance or 'matrix', known as inclusion bodies (IBs), long known as Negri bodies commonly found in brain tissue as well as tissue culture, is formed. The formation of IBs comprising filamentous matrix substance (generally N-P complexes), which precedes virus particle formation in neurons of the infected brain, is often a hallmark for the diagnosis of rabies. The association of M with the newly formed transcriptionally active RNP selectively inhibits further transcription and replication of the viral genome and localizes the RNP at the cellular membrane where the glycosylated trimeric G is concentrated and M interacts with G. Finally, M begins to alter the structure of the RNP by condensing it into a tightly coiled 'skeleton-like' (RNP+M) form in which the polymerase activity is 'frozen' in place. Thereby, M plays an important role by covering the RNP and giving the virus particle its 'bullet' shape. In the final stages of virus assembly the mature virion acquires its lipid envelope derived from the host cell's plasma membrane, with the trimeric G spikes embedded in it as the virion buds through the membrane.

Epidemiology of Animal and Human Rabies

The natural course of RABV transmission is from animal to animal and hence it is principally a zoonotic disease. On the occasions that RABV spreads to humans it is primarily the consequence of an attack by an aggressive infected animal biting the human and transmitting the virus present in saliva, which comes from the animal's salivary glands. The reservoir for all RABV and non-RABV

lyssaviruses is the animal species pool that circulates the various lyssavirus species. But not all populations of terrestrial carnivores serving as reservoir hosts for rabies are affected proportionately. Transmission of RABV and the non-RABV lyssaviruses is usually among animals of the same species with cross-species transmission to other mammals usually depending upon direct interactions with infected individuals of the reservoir host species. Such virus spillover from one host species to another can and has led to viral evolution and adaptation in a new host species over broad timescales. Bat lyssavirus variants, for example, sporadically spill over to infect wild and domestic animals. New host species, such as red foxes on Prince Edward Island, Canada, and Nova Scotia, Canada, and striped skunks in Arizona, have sustained transmission of bat variants of RABV within terrestrial carnivore populations until possible natural extinction. Extinction can occur because of disappearance of the virus or the virus reaching undetectable levels within the local species population, or by vaccination control programs as has occurred with skunk rabies in Arizona. Initial epidemics of rabies in animals are typically the largest in a series of epidemics that emerge over time. As 'wildlife' rabies enters into a new region to infect previously naive populations, a series of successively smaller epidemics may occur at increasing frequency. This has occurred with red fox rabies in regions of Europe and with a raccoon-adapted variant of RABV in regions of the USA. In the mid-1970s, the raccoon-adapted variant was introduced into the mid-Atlantic region of the United States as a consequence of transporting raccoons unsuspected of incubating rabies from a couple of southeastern states for the purpose of restocking dwindling local populations. These animals were moved, apparently while incubating the raccoon-adapted RABV variant, and when placed among naïve animals in state parks and game reserves soon spread the virus to other raccoons that over time and distances transported the virus northward to Maine and Ontario, Canada and westward to Ohio, creating the most expansive outbreak of animal rabies so far recorded. Typically, regions of higher population densities of wildlife species suffer greatest population depression due to rabies transmission and the highest incidence of disease during the initial epidemic. In the United States, raccoons have been the wild animal species most frequently diagnosed as rabid since the early 1990s, whereas skunks and foxes were the most frequently reported rabid cases during previous decades, 1960–90s and 1950–60s, respectively (Figure 4). Rabies among skunks in North America has a long history, since the 1800s, as a source of human rabies. Currently, two RABV variants that circulate within specific wildlife species circulate among skunks in the central United States; one of these, the North Central Skunk variant, also occurs in central and western Canada, and the other RABV variant circulates among skunks in California. Periodic epizootics (periods of increased disease activity) or epidemics of rabies in skunk populations that occur in other states tend to drive the cyclic variations in skunk population numbers (Figure 5).

Bats are perhaps the most unique group of wildlife mammals to transmit RABV and non-RABV lyssaviruses to carnivores and humans. Currently, there are 12 uniquely identifiable lyssavirus species and a further two recently described viruses that appear to cause a rabies-like pathogenesis in humans and terrestrial carnivores. Only two of these lyssaviruses, MOKV and IKOV, have not yet been detected in bat species. Among the many families, subfamilies and genera of bats that comprise the order Chiroptera, it is the vampire bat that preferentially attacks livestock and transmits rabies sporadically to cattle. Observations linking vampire bats to rabies epidemics among terrestrial animals, particularly in South and Central America, causing paralytic rabies in cattle, the preferential target species of vampire bats, go back more than 90 years. Occasionally, vampire bats bite and infect humans, particularly in many South and Central American countries, but other chiropteran hosts historically associate more with

Figure 4 Rabies among wildlife animal species in the United States, 1951–2010. The number of reported cases of rabies among selected wildlife animals in the United States, 1951–2010, as reported through national surveillance (data obtained from annual CDC surveillance reports). Reproduced from Hanlon, C. A., Childs, J. E. (2013). Epidemiology. In: Jackson, A. C. (ed.) *Rabies*, 3rd edn., pp. 61–121. San Diego, CA: Elsevier, Academic Press, with permission.

Figure 5 Distribution of rabies virus (RABV) variants in the United States. Common species of terrestrial carnivores among wildlife serving as reservoir hosts. The geographic occurrence of two skunk rabies variants is represented as Northcentral Skunk and Southcentral Skunk. In addition to this distribution of RABV variants is the reservoir present in species of bats, which covers the entire continental United States. Reproduced from Childs, J. E., Real, L. A. (2007). *Epidemiology*. In: Jackson, A. C., Wunner, W. H. (eds.) *Rabies*, 2nd edn., pp. 123–199. San Diego, CA: Elsevier, Academic Press, with permission.

transmission of rabies to animal and human populations. Clinically, RABV transmitted by vampire bats to cattle, humans, and other bats cause ‘paralytic’ disease and virtually never ‘furious’ rabies (‘Human rabies’). Paralytic rabies in cattle starts with signs of posterior unequal coordination followed in later stages with anorexia, bellowing, weakness in the hind legs, and other signs of brain damage. Finally, ascending paralysis, temporary cessation of breathing, and death occur. Humans can experience similar clinical signs and fatal outcome because of contact with infectious saliva from the bite or by inhalation of aerosolized saliva of a rabid vampire bat. It is not known whether some specific property or properties of the RABV variant circulating among vampire bats might be responsible for this rather oblique presentation of the disease. Bats are the second most common transmitters of rabies to humans. Human rabies resulting from insectivorous bat species, particularly in the New World, did not appear until the 1950s. The first human case to be particularly identified with an insectivorous bat occurred in 1953, in Florida, and since then the number of rabid bats reported in the United States has increased dramatically. The association of classical RABV with insectivorous bat species across the New World over the past 60 years has been as diverse as there are different insectivorous bat species that appear to serve as virus reservoirs for lyssaviruses in the New World compared to that of the Old World. This diversity of RABV variants that has emerged through natural infections of insectivorous bats has manifested itself in different clinical signs of the disease, i.e., aggression, weakness, and anorexia with relatively short morbidity periods (4–20 days). With highly sophisticated genetic analyses of the different lyssaviruses isolated from insectivorous bats, it has been possible to differentiate the virus variants that associate with bats, as well as terrestrial hosts such as red fox, skunks and raccoons, so that the virus variant can now be correlated with a particular bat species and probably the country where the transmission occurred. Human infection caused by RABV variants from insectivorous or suspected insectivorous bats has been increasing in North America (at least 69 cases identified between 1950 and 2010) now that rabies in the domestic dog population has been eliminated.

The dog is the most common animal to transmit rabies to humans as well as to other carnivores in all regions of the world in which public health concern is highest. When dog rabies is reduced by effective disease control measures, such as mass vaccination of both domestic and stray dogs, human rabies cases also decline. Implementation of control programs and policies for bat rabies, on the contrary, has not been possible, largely because regimens for administration of vaccines in bats have not been adequately developed, or have been much less widely implemented. In contrast to RABV variants found predominantly in wildlife in North America (the United States and Canada) and Western Europe, the greatest dissemination of RABV in many locations in the world has been by dogs. The domestic dog continues to be the major reservoir species for RABV throughout Africa and Asia, and to a lesser extent in South America and Latin America. The similarity of canine RABV isolates from South America, Africa, Eastern Europe, and parts of Asia suggests that rabies in dogs arose from a common source, perhaps from a single origin in the Palearctic region that includes Europe, the Middle East, and northern Africa. Canine rabies was imported from Europe to the New World in the eighteenth century during the time of the Spanish dominion in southern parts of North America and in Mexico as early as 1709. Outbreaks of dog rabies in South America followed early in the nineteenth century in Peru (1803) and Argentina (1806). Later, epidemics of canine rabies came in 5- to 6-year cycles in South America. Feral, stray, and neighborhood dogs contribute to free-ranging populations in both developed and developing countries. Interestingly, young dogs, frequently less than 1 year of age, which have not received a complete course of rabies vaccination, contribute in a major way to rabies outbreaks, particularly during major mass vaccination campaigns in canine rabies endemic regions.

The greatest number (>99%) of human rabies deaths result from infection by RABV maintained by domestic dogs and transmitted by dogs that bite humans and these occur mostly in tropical areas in developing countries of the world, where accurate estimates of human rabies deaths are impossible to obtain by surveillance methods. Regional laboratories are also inadequate or nonexistent for systematic detection and laboratory confirmation of human or animal rabies cases. Recent estimates by the World

Health Organization (WHO), nevertheless, suggest that the highest incidence of human rabies deaths is 55 000 annually in Africa and Asia from being bitten by RABV-infected dogs. The global public health burden and cost of canine rabies in Africa and Asia alone, based on direct medical expenses and indirect costs borne by patients seeking postexposure vaccine treatment (PET), amounts to roughly US\$196 million/year and US\$289 million/year, respectively. Worldwide each year an estimated 7 million people bitten by suspect rabid dogs increases the high demand for expensive postexposure prophylaxis (PEP) and PET.

Control and Prevention of Rabies in Domestic and Wildlife Animals

Control and prevention of rabies in domestic animals has been most successful in countries that advocate strong veterinary and public health programs and have the cooperation of people who take their responsibility for animal pets seriously. Nationwide vaccination programs together with rules or laws to enforce the elimination of stray dogs and cats and use of quarantines in rabies-free countries have done the most to keep rabies from spreading. To be effective, these measures as well as the oral immunization approach for wild animals must reduce the number of unvaccinated animals to a level at which rabies transmission is interrupted and this level must then be maintained.

Preventing the spread of rabies to susceptible animals and humans continues to be a major battle for biologists and public health officials throughout the world. Persistence of multiple variants of RABV and non-RABV lyssaviruses in wildlife animal reservoirs presents a continuing challenge to those dealing with medical, veterinary, and wildlife management. To control rabies at its source is to control the disease in wildlife vector species, and this may be the most challenging and difficult task of all. Many techniques have been tried over the past three decades, beginning with the control of rabies in foxes in Western Europe using the concept of oral vaccination and baits carrying vaccine to immunize free-ranging animals. Almost every species of mammal that acts as a vector for the disease requires a unique approach depending on many factors, including density of wildlife populations, restriction of movement, food sources, and functions of the species to prevent a particular species from becoming infected. On the contrary, the impact that vaccines have had on protecting domestic animals, causing a dramatic reduction in the incidence of canine and human rabies, clearly holds great promise for the prevention and ultimate control of rabies in wild animals.

The main transmitters of wildlife rabies throughout the world are the wild carnivores. These animals are highly susceptible to rabies: they excrete virus in the saliva and live in high-density populations, and the long incubation period of the virus ensures maintenance of the infection. The most significant terrestrial wild carnivores transmitting rabies in the world are the red fox (*Vulpes vulpes*) in Central and Western Europe and the red fox and raccoon dog (*Nyctereutes procyonoides*) in Eastern Europe. Foxes (*V. vulpes* and *Urocyon cinereoargenteus*), skunks (predominantly *Mephitis mephitis*), and raccoons (*Procyon lotor*) are the major animal vectors in various parts of North America, and wolves, stray dogs, mongooses (*Herpestes auropunctatus*), meerkats, and polar foxes in other areas and countries of Africa, Asia, and Central and South America. Establishing well-organized and well-managed programs with extensive national and international cooperation among veterinary and public health personnel who share as a common goal the control of rabies in wild animals, from local eradication to inhibition of spread into uninfected areas, will undoubtedly be more difficult than controlling rabies in domestic animals. Several European and North American team efforts, nevertheless, have made significant progress in evaluating the efficacy and safety of vaccines and vaccine delivery systems for oral immunization of wild carnivores. The progress is such that it can be said that the oral immunization method can be an effective and practical approach for the elimination of enzootic rabies in terrestrial animals, one species at a time.

The Blueprint for Rabies Prevention and Control

Experts in rabies management worldwide formed the 'Partners for Rabies Prevention' (PRP) initiative and developed a 'blueprint' to provide government officials and their public health professionals, veterinarians, scientists, medical doctors, and other experts in diagnostics, virology, epidemiology, ecology, immunology, animal welfare, outreach health educators and communicators with advice in the form of a comprehensive set of guidelines and the necessary encouragement and support to develop their own national canine rabies elimination programs. This online document of operating procedures is designed to help governments plan, implement, evaluate, and sustain canine rabies elimination programs as described in 'The Blueprint for Rabies Prevention and Control' (available at <http://www.rabiesblueprint.com>). Information to help governments focus their planning, implementation, evaluation, and ability to sustain canine rabies elimination programs, in particular, is contained in one section of the blueprint (www.caninerabiesblueprint.org). The Canine Rabies Blueprint, which was established in 2010, is a powerful toolkit in simple language that is freely accessible to a wide range of users. This type of 'one health' approach to canine rabies control and elimination is expected to grow in interest and have considerable impact on local endemic canine rabies in high-risk countries.

Human Rabies

Clinical Signs and Symptoms

Humans infected with RABV develop classical encephalomyelitis, often referred to as 'furious' or 'encephalitic' rabies, in approximately 80% of the cases and the rest (20%) exhibit a paralytic form of the disease. Rabies in humans usually develops 20–90 days after

exposure, although occasionally the disease develops after only a few days and rare cases have occurred after a year or more following exposure. The clinical illness in humans, which follows such a variable and sometimes prolonged nonsymptomatic incubation period, usually begins with a prodromal phase, which may last 2–10 days. At this point the symptoms are almost entirely nonspecific, comprising fever, malaise, anorexia, nausea, vomiting, diarrhea, sore throat, cough, myalgia, and headache. After the prodromal period, signs of nervous system involvement develop, leading to an acute neurological phase, including intermittent hyperactivity marked by agitation lasting 1–5 min, occurring spontaneously or triggered by a variety of tactile, auditory, and visual stimuli, disorientation, hallucinations, seizures, bizarre behavior, nuchal stiffness, and paralysis. Other abnormalities include muscle fasciculation (particularly near the site of the exposure), hyperventilation, and hypersalivation. Hydrophobia, a term often used to describe rabies involving both severe thirst and fear of water, is regarded as a unique characteristic and most specific manifestation of rabies in humans, and appears to develop in 50–80% of patients with encephalitic or furious human rabies. The mental status of the patient gradually deteriorates during a period of 2–12 days until the onset of coma, which may last for hours or months, or an abrupt death due to cardiac or respiratory arrest. With intensive medical support, cardiac and respiratory arrest may not occur, and the patient may experience rare recovery. The incubation period (from exposure to onset of clinical signs of disease) in rabies has a greater length and variability than in most other infectious diseases, which can cause considerable stress to the patient. Severe facial bites and multiple bites to other areas of the body tend to have shorter incubation periods. In cases of long incubation periods, it is often difficult for the patient to recall a bite exposure, particularly if the bite was from an insectivorous bat, or the patient becomes unintelligible from the disease. From cases of untreated humans who developed rabies following known animal bites, the highest number (50–80%) occurred from bites to the head, the next highest number (15–40%) from bites to the hand or arm, and the fewest (3–10%) from bites to the leg. The risk from scratches or contamination of minor wounds with saliva is about 0.1%.

In paralytic (or ‘dumb’) rabies, muscle weakness develops early in the course of the disease. The paralysis may start in the bitten extremity and spread to other extremities, but is not necessarily related to the anatomical site of the animal bite (exposure). Consequently, rabies is often misdiagnosed in this clinical form, especially if there is no history of animal exposure. At the onset of this clinical form of rabies, patients are alert with a normal mental status. They may have local pain, paresthesias, or pruritus at the bite site even though sensory perception upon examination may be normal. Muscle fasciculations may be present and facial muscles become weak bilaterally. The clinical picture may be confused with the Guillain–Barré syndrome. Unlike Guillain–Barré syndrome, urinary incontinence is common and pain and sensory disturbances may occur in paralytic rabies.

Other lyssaviruses, in addition to RABV, have also caused rabies. Only LBV, which was first isolated from fructivorous bats in Nigeria, has not been associated with human rabies. Four other lyssaviruses recently isolated from bats, ARAV and KHUV, which were isolated from bats in Central Asia, and IRKV and WCBV, which were isolated from bats in Russia, have also not been associated with human disease. MOKV, which was isolated from shrews in Nigeria, was associated with meningoencephalitis, without the typical features of brainstem involvement seen in classical rabies, in a 6-year-old girl who died in Nigeria in 1971 after a 6-day illness. Another patient, a 3 1/2-year-old girl from Nigeria, who presented with a sudden onset of fever and convulsions, made a complete recovery. In this case, MOKV was isolated from her cerebrospinal fluid (CSF), although it is questionable whether cross-contamination of her CSF might have occurred since the shrew isolate of MOKV was handled in the same laboratory. In 1970, a 31-year-old man from rural South Africa developed an illness that was indistinguishable from rabies. The patient’s illness was characterized with fever, excessive sweating, hydrophobia, and spasms of his face, arms, and torso. He was confused, irritable, and periodically aggressive. He died 5 days after the onset of illness. The man had been bitten on the lip by a bat 4 weeks earlier. The virus that was isolated from the patient’s brain after death was DUVV. In 1985, two cases of rabies-like illness occurred in Europe; one was an 11-year-old girl from Belgorod, Russia, who was bitten on the lip by an unidentified bat, and the other was a 30-year-old man, who was a zoologist from Finland. Both died with signs indistinguishable from that of rabies. The virus isolated from the girl was called *Yuli virus* and classified as EBLV-1, and the virus isolated from the man who died 23 days after the onset of illness was like other enzootic European bat RABV isolates and was classified as EBLV-2. In 1996, a 39-year-old woman from Australia died after a 20-day illness. She sustained numerous scratches to her left arm over 4 weeks while she cared for fruit bats and apparently had been bitten by an insectivorous bat prior to the onset of her illness. Her illness was marked by progressive left arm weakness that later developed into progressive limb and facial weakness with reduced tendon reflexes and fluctuations in her level of consciousness prior to her death. The virus she was infected with was identified by the reverse-transcription polymerase chain reaction (RT-PCR) assay, perhaps the most frequently applied test presently available, and found to be identical to ABLV, which had been identified in flying foxes (fruit-eating bats). This patient had rabies that typically involved the brainstem and quickly progressed to diffuse brain involvement. Two years later, in 1998, a 37-year-old woman from Queensland, Australia, experienced fever and paresthesia in her left hand and pain in her left shoulder, along with a sore throat and difficulty in swallowing for 5 days before she was admitted to hospital. She had pharyngeal spasms, evidence of autonomic instability, and progressive neurologic deterioration before she died 19 days after onset of her illness.

Rabies Diagnosis

An estimated 7–10 billion diagnostic tests of all types for rabies are performed in the laboratory each year in the United States alone, most frequently for the postmortem examination of animals that have either bitten a person or in some other way potentially caused human exposure to the disease. Evidence of RABV infection in a contact animal (and sometimes in an exposed person subjected to an antemortem diagnosis of rabies), based on a positive diagnostic test, prompts administration of rabies PET and PEP to the exposed person and any other persons who had direct contact with the exposed person, respectively. A skin biopsy from the

nape of the neck that includes several nerve-innervated hair follicles is often the best sample for a human antemortem diagnosis of rabies using a direct fluorescent antibody (DFA) test or RT-PCR assay. Fresh saliva is another sample source for RT-PCR assay, while serum and CSF are suitable for the detection of anti-rabies antibodies that can be assayed in a rapid fluorescent focus inhibition test (RFFIT). Often, a positive diagnosis of RABV in animals, as in the observation of rabies viral antigen in the brainstem at the level of the medulla, pons, or midbrain, also initiates the appropriate management of exposed domestic animals, including booster immunization of previously immunized animals and euthanasia or quarantine of unvaccinated animals.

While various types of diagnostic tests may be performed, diagnosis of rabies based upon clinical presentation alone may be difficult to discern. Clinical symptoms or signs of human rabies often occur long after exposure to the virus and can be difficult to distinguish from encephalitis caused by other viral infections, such as poliovirus or canine distemper virus in humans, or may be confused with Guillain-Barré syndrome. RABV infection can be inferred in some cases from indirect evidence, such as the demonstration of RABV-neutralizing antibody in the serum of an unvaccinated individual or antibody in CSF. Specific histopathologic changes in postmortem examination, namely the presence of Negri body inclusions in neurons of the CNS, can provide microscopic evidence of RABV infection, but only with a low degree of sensitivity. A more specific indication of RABV infection from a postmortem examination of humans suspected of having rabies is the direct visualization of RABV particles in brain tissue and CSF or saliva using EM. Similarly, specific indications of rabies can be used to determine the treatment of humans based on examination of brain specimens taken from contact animals suspected of having rabies after they have been euthanized by any humane method that does not damage the head. Other indications can be made in postmortem tissue (from animal or human) prepared as a smear, impression, or section or from CSF or cultured cell monolayer infected with the suspected virus. These are detection of the viral proteins (antigens) by DFA and indirect fluorescent antibody (IFA) tests and viral genome RNA using genetic hybridization probes and RT-PCR techniques. Immunoglobulin (or viral antigen-specific monoclonal antibody (MAb)) molecules labeled by covalent chemical attachment of a fluorescent tag to produce a fluorescent-MAb conjugate permit visualization and localization of the target protein in tissue preparations or saliva. These viral antigen-specific antibody diagnostic reagents, which interact specifically with the desired viral antigens (targeting specific epitopes on the proteins) in the DFA and IFA tests, provide a more definitive diagnosis of rabies infection in the contact animal and exposed human. The most common confirmatory test is cultivation of virus by inoculation of laboratory (test) animals or cell culture. The mouse inoculation test (MIT) is a sensitive and reliable procedure to confirm the presence of virus in pieces of the brain that test positive by the DFA or IFA methods. Direct detection of the viral genome or virus-specific mRNAs by hybridization with nucleic acid probes applied to tissue sections (*in situ* hybridization) requires close attention to the specificity of the probe sequences that are used to anneal with its viral positive or negative RNA strand target sequence. Since no commercial sources of RABV-specific probes are available, all probes must be developed for the laboratory, and special attention must therefore be paid to the diversity of lyssavirus strains that might be present in the specimen.

Rabies Pathogenesis and Histopathology

The pathogenetic process of rabies usually begins with the introduction of virus-laden saliva into a bite or scratch wound inflicted by a rabid animal. The incubation period after the bite can be extremely variable depending on the relative susceptibility of the species, the location of the wound (to the head vs. extremities), and the depth and location of virus deposit in the wound. In humans, the incubation period is usually 20–90 days, more generally 15 days to 1 year, but cases have been described recently in which the extremely sophisticated, highly sensitive, and precise antigenic (using MAbs) and genetic (employing the RT-PCR technique) diagnostic methods established that the incubation period could last several years. Other routes of infection have included intranasal (in animals that sniff) and oral routes (among bats that spray in high-density cave dwellings) as well as corneal transplants (in human cases). Because the neural routes from mucosal membranes and the eye to the CNS are relatively short, the virus has almost direct access to the brain from these tissues. RABV in natural infections does not establish a viremia.

Perceptions of what happens to the virus at the site of entry *in vivo* and the events that precede the transit of virus toward the CNS (the ‘neural phase’) are still vague. One puzzling aspect of preneural RABV infection is the sequestering of virus at the site of inoculation. Macrophages *in vitro* can be persistently infected with RABV, but it has not been demonstrated in animal models that macrophages *in vivo* sequester RABV. Evidence of viral antigen accumulating in striated muscle in experimental animals after intramuscular inoculation of RABV has suggested that muscle becomes a potential initial site of virus replication although this has not been observed in humans. The ‘preneural phase’ of virus infection in muscle is usually confined to a small number of myocytes close to the inoculation site and produces few infectious particles. Any shedding of virus into extracellular spaces around myocytes, of course, makes this virus vulnerable to the PET with anti-rabies antibody and vaccine.

Exposed sensory nerve endings of neuromuscular or neurotendinal spindles deep in muscle are the most likely sites of virus entry into the peripheral nervous system after virus replication in muscle. The primary site of virus attachment might actually be nerve endings leading directly to neuronal infection in badly torn muscles of a bite wound. Similarly, the many sensory nerve endings of epithelial and subepithelial tissues exposed by superficial abrasions of skin and mucous membranes may also serve as primary sites of virus entry. The entry of RABV into peripheral nerves begins the ‘neural’ or ‘neuronal’ phase of infection, which is characterized by the centripetal movement of virus exclusively within axons to the CNS. Schwann cells and perineural elements do not appear to be infected.

Virus migration from peripheral sites on the body to the brain is suspected to occur passively in the axoplasm of peripheral motor and perhaps sensory nerves (centripetal passage to the brain) at the estimated rate of retrograde axoplasmic transport (3 mm h^{-1} or between 50 and 100 mm day^{-1}) in peripheral nerves. Evidence that the RABV P (phosphoprotein) of the RNP complex interacts with LC8, a component of both cytoplasmic myosin V and dynein, which are involved in actin-based transport (important in early steps of

viral entry) and microtubule-based transport in neurons, respectively, has led to speculation that the RABV P–dynein interaction may be fundamentally important in axonal transport of RABV. Other mechanisms of virus transport may facilitate its spread (e.g., movement of virus across cell-to-cell junctions, including synaptic junctions). Observations of virus budding on axonal membranes and virus particles accumulating intra-axonally at nodes of Ranvier as the virus progresses to the brain support the possibility of other mechanisms of virus transport. The ascending paralysis seen in many infected animals and humans reflects the progressive infection of dorsal root ganglia of the CNS. The virus ascent toward the brain has been confirmed by sequential immunofluorescence studies. The ability of virus to spread to the CNS from a peripheral site (its neuroinvasiveness) is an important component of the ‘neurovirulence’ characteristic of the virus. Studies have shown that while the spread of pathogenic (virulent) and nonpathogenic (avirulent) viruses *in vitro* (spreading from cell to cell in cell culture) reflects their ability to spread *in vivo*, the pathogenic virus spreads more rapidly in the CNS and infects more neurons than the avirulent virus *in vivo*. Once RABV infection enters the brain, the virus spreads rapidly along neuroanatomical pathways, spreading within the CNS as in the peripheral nerves.

Inflammatory lesions caused by perivascular infiltration of lymphocytes, macrophage, and occasionally polymorphonuclear cells are the most common and frequently noted histological signs of change in the spinal cord and brainstem of animals and humans infected with RABV. The ganglionic changes observed in rabies, although not exclusively confined to rabies, could serve as diagnostic lesions for rabies, because they are not encountered in diseases that must be considered in the differential diagnosis of rabies. The morphologically distinct lesions that are significant in rabies diagnosis are the specific eosinophilic inclusion bodies (Negri bodies) found within neurons of peripheral and basal ganglia of the spinal cord, in the pons and medulla of the brainstem, in the cerebral cortex and thalamus and Purkinje cells of cerebellum, and in ganglion cells of Ammon’s horn of the hippocampus. Signs of active transport of virus in the brain include replication in the neurons, budding from the plasma membrane, and release into tissue interstitial spaces. The virus appears to infect susceptible cells by viropexis or direct cell-to-cell transmission. Once delivered in the extracellular spaces of the brain, the virus can presumably spread by passive transport over relatively long distances through intercellular spaces large enough to pass virus by interstitial fluid movement. Virus that is transmitted directly from one nerve cell to a contiguous nerve cell could also spread and result in the same long-distance movement because of the many long, intertwined neuronal processes that connect in the brain.

Surprisingly, despite the severe neurological signs of clinical rabies (Human rabies) the neuropathological findings are generally mild (see below). This suggests that RABV-infected neurons become dysfunctional without developing major morphological changes or positive terminal deoxynucleotidyl transferase dUTP nick-end-labeling (TUNEL) staining, indicating fragmented cellular DNA that is normally associated with apoptosis. If true, what is the fundamental underlying basis for the proposed neuronal dysfunction, if not apoptosis, that would account for the severe clinical neurological signs observed in rabies? One hypothesis has been that apoptotic cell death in the CNS of humans and in experimental animals in which apoptotic changes have been examined is caused by RABV infection. After finding evidence of oligonucleosomal DNA fragmentation typical of apoptosis and that cell death was concomitant with expression of the rabies viral G, an (unexpected) inverse relationship was found between the pathogenicity of the virus (comparing the virulent phenotype with the avirulent phenotype) and apoptosis. In other words, apoptosis may be a protective rather than a pathogenic mechanism in RABV infections both *in vitro* (studies with cell culture) and *in vivo*. The less pathogenic (avirulent) viruses induce more apoptosis than the more pathogenic (virulent) viruses *in vitro* as well as *in vivo*, using peripheral routes of inoculation. In RABV infection the mechanisms involved in the ensuing cell death or survival of neurons, both *in vitro* and in animal models using different viral strains and routes of inoculation, are clearly complex.

Once the virus begins to spread from the brain in the final phase of rabies infection, the tropism of infectious virus changes and the virus is delivered to a variety of extraneural and nonneural tissues. The centrifugal (outward) spread of virus generally occurs via the same axoplasmic transport routes that were used for the centripetal (inward) passage of virus inward to the CNS. The spread of RABV in the absence of CNS infection is virtually nonexistent. Among the most heavily infected tissues following propagation of virus in the CNS are the end organs in oral and nasal cavities, and the head and neck. Infection may be found in free sensory nerve endings of tactile hair follicles or in epithelial cells of hair follicles in the skin. To take a skin biopsy from the nape of the neck is one of the best diagnostic methods of confirming an antemortem diagnosis of rabies in humans (‘Human rabies’) (see Rabies Diagnosis). The fact that rabies antigen is occasionally detectable in skin biopsy and in corneal impressions is evidence of its nerve-mediated dissemination.

Infection of the salivary glands by dissemination of virus from the CNS is extremely important in the life cycle of the virus because it is required for effective transmission of disease. Virus titers in the salivary glands often exceed those in the brain. In some animal species, the salivary glands become infected before the signs of CNS infection become apparent, and at the height of salivary gland infection, large amounts of fluorescent viral antigen may be detected in individual acinar cells, in cell clusters, and occasionally in the entire acinus.

Presently, the molecular basis of RABV pathogenesis is linked to surface G, which also plays an important role in the initiation of RABV infections as the viral attachment protein that interacts with the cell surface receptor. Through selection of neutralization-resistant variants of RABV (using virus-neutralizing MAbs against G) that lost their virulence phenotype and by identification of single amino acid changes in G, the pathogenicity of the virus appears to correlate with the presence of an epitope on G within antigenic site III. The amino acid substitution in the mutant that renders the virus nonpathogenic for adult mice was located at position 333 of RABV G where arginine is normally found. Isoleucine at position 333 in the fixed RABV Evelyn–Robitnicki–Abelseth (ERA) strain variant and glutamine or glycine in the fixed rabies CVS strain variants replaced arginine at position 333 of RABV G in the respective pathogenic parent viruses. Several other fixed RABV strains including attenuated viruses that were not selected by MAbs but resisted neutralization by specific MAbs (194-2 and 248-8), such as the Flury high egg passage (HEP) and Kelev strains,

also substituted isoleucine, glutamine, or glycine for arginine 333. Other discrete amino acid substitutions for arginine 333 include methionine and serine. The biological relevance of arginine at position 333 of RABV G or its influence on the pathogenic mechanism responsible for the restricted neurotropism of RABV infection is not completely understood. Experiments have suggested that the neural routes of entry to the CNS and the rate of virus spread may differ depending on the amino acid at position 333, but as yet the complete story has not been told.

Many of the dominant pathologic features of RABV infection were first described in the early 1870s to early 1990s. With the introduction of EM and immunohistochemistry, pathology studies have continued to provide key insights into our understanding of rabies. Although the clinical outcome of RABV encephalomyelitis might suggest severe degrees of destruction, the histopathological changes observed in the CNS are typically relatively mild. Some inflammatory cell infiltration of the leptomeninges usually occurs in human rabies cases. Infiltrates are composed of lymphocytes and monocytes, small numbers of plasma cells, and a predominance of neutrophils when inflammation is intense. Perivascular 'cuffing' is seen predominantly in gray matter, especially in the brainstem and spinal cord, marked with infiltrates of lymphocytes and monocytes. The development of neuronophagia (accumulations of activated microglia/macrophage in the process of phagocytosing degenerating and/or dying neurons) is typical in many rabies cases. Microscopic accumulations of proliferating microglia/monocytes known as Babes nodules (first described by Babes in 1892) can be observed in gray matter of the medulla oblongata in human rabies cases. However, because Babes nodules can be present in other viral encephalitis and other infectious disorders they are less reliable for rabies diagnosis. On the other hand, Negri bodies, described in the 1903 by Adelchi Negri are more of a classical hallmark of cytological features in rabies. Stained with hematoxylin- and eosin, they appear as dense, well-defined, oval or round (typically 2–10 μm in diameter, but can be 0.5–27 μm) eosinophilic intracytoplasmic inclusions (Figure 6). Although found in 50–90% of human rabies infections, especially in hippocampal neurons and cerebella Purkinje cells, their significance in the pathogenesis of rabies is not as obvious. The ultrastructure of Negri bodies includes randomly orientated viral NC (source of RABV N for antigen diagnosis) resembling large aggregates of granulo-filamentous matrix material occasionally interspersed with bullet-shaped virus particles giving the bodies an overall granular, electron dense manifestation. They are usually found in areas of the CNS where there is little inflammation, and less frequently seen in degenerating neurons and/or in association with inflammatory foci.

Histopathology in peripheral nerves as virus spreads through the peripheral nervous system (PNS) is associated with inflammatory, reactive, and degenerative changes in structural components of the PNS. Changes in sensory and autonomic ganglia as well as a neuronopathy (degeneration and loss of sensory and autonomic neurons) leading to degeneration of spinal and peripheral nerve fibers and routes have particular diagnostic utility.

Rabies Vaccine Prophylaxis

First Line of Protection Against Rabies – Preexposure Prophylaxis

Rabies is a preventable disease in humans if the right precautions are taken to ensure pre-exposure prophylaxis (PrEP). Those who consider themselves to be at increased risk of possible exposure to rabid animals, especially unvaccinated free-roaming dogs should

Figure 6 Negri bodies stained with hematoxylin and eosin (HE) in perikarya of (A–C) cerebellar Purkinje cells and (D, E) pyramidal neurons in the cerebral cortex of human rabies cases. The arrow in (D) indicates a Negri body in an apical dendrite. (magnifications, A $\times$ 315, B $\times$ 460, C $\times$ 550, D $\times$ 730, E $\times$ 865). Reproduced from Rossiter, J. P., Jackson, A. C. (2013). Pathology. In: Jackson, A. C. (ed.) *Rabies*, 3rd edn., pp. 351–408. San Diego, CA: Elsevier, Academic Press, with permission.

be administered PrEP vaccination. Veterinarians and animal handlers because of their frequent and often unsuspecting contacts with domestic as well as wildlife animals, and those persons who by the nature of their work, hobbies (e.g., caving) or travels to rabies endemic areas put themselves at high risk of exposure and infection, particularly where access to timely PEP is not an option (e.g., no medical clinics) should receive the full regimen of inoculations. PrEP consists of a series of three doses of vaccine, given either intramuscularly (IM) or intradermally (ID) on each of 3 days; 0, 3, and either day 21 or 28. Antibody titers of 0.5 international units (IU)/ml or higher are considered to be protective against rabies. A single booster dose of vaccine would be necessary should the titer fall below this minimum titer.

First Line of Defense After Exposure to Rabies – Postexposure Prophylaxis

Since the incubation period may be variable and often sufficiently long following the peripheral inoculation of RABV from an animal bite, depending on the location and severity of the bite exposure, it is possible to neutralize the virus at the wound site with anti-rabies antibody before the virus enters and spreads along neuronal pathways to the CNS. According to WHO recommendations, PEP must be administered to every patient that has been exposed to rabies. Immediately or as soon as possible after an exposure to a potentially rabid animal, it is essential to start PET and PEP by first cleaning the wound using proper wound cleansing procedures as a first line of defense against RABV infection. It is important in this procedure to inactivate as much as possible of the RABV that may have entered the wound. Proper wound cleansing involves thorough washing of the wound or mucous membrane for at least 15 min using soap, water, detergent, povidone iodine, or another antiviral substance. If soap and detergent are not available the wound should be flushed with copious amounts of water. After the wound has been thoroughly cleansed, rabies immunoglobulin (RIG) (virus neutralizing antibody) must be injected into and around the bite (wound) or mucous membrane sites to neutralize virus deposited with saliva from the animal's bite. Two types of RIG are administered to patients globally; human rabies immunoglobulin (HRIG) is used more frequently in industrialized countries whereas equine rabies immunoglobulin (ERIG) is more frequently administered to patients in developing countries. To administer the RIG properly, the full dose of 20 IU kg⁻¹ of body weight of HRIG and 40 IU kg⁻¹ of body weight of ERIG must first be injected directly into as well as around the wound site in as many places as anatomically feasible. Any HRIG or ERIG that is left over after infiltrating the wound sites should be administered deep intramuscularly at a site that is distant from the vaccine inoculation site so as not to interfere with (neutralize) the vaccine dose that is also given at this time for prophylaxis (infection prevention).

Rabies vaccines available in developing countries for PEP are mostly nerve tissue vaccines (NTVs) produced from the brain tissue of infected sheep or mice although these are gradually being replaced by more immunogenic and less reactogenic cell culture-based rabies vaccines (CCVs), particularly in large cities. The problem with the modern cell culture vaccines is they cost more to produce, limiting their use to those at the highest risk of RABV infection, who ironically are often among the poorest of society. The postexposure vaccination regimens recommended for CCVs use either IM or ID routes of inoculation of which the latter is an option for reducing the dose administered and the cost of treatment. The first dose of vaccine is given with RIG administered in and around the wound site. It is important to note that there is sufficient data to insure that when used in conjunction with prompt appropriate wound care along with RIG, the postexposure vaccination regimens recommended by the global WHO Expert Committee on rabies can prevent death from rabies. There are two IM and two ID postexposure vaccination regimens recommended for use with cell culture rabies vaccines. In the United States, the Advisory Committee on Immunization Practices (ACIP) recommends a four-dose rabies vaccination regimen with human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV) administered IM on days 0 (as soon as possible after exposure), 3, 7, and 14 instead of the Essen regimen, which stipulates five IM doses, previously recommended for use in North America. The Essen regimen is also used in Europe and in those parts of Asia and Africa where ID administration of rabies vaccines is not yet approved. The Essen regimen specifies one full dose IM on days 0, 3, 7, 14, and 28. The Zagreb regimen, which specifies two doses IM on day 0 (one in each deltoid) and one additional dose on days 7 and 21, reduces the number of doses required from five to four, and, importantly, it reduces the number of visits to get the rabies vaccine from five to three. The Zagreb regimen is used in some European countries.

The WHO-recommended ID vaccination regimens, which use reduced doses of vaccine, were developed to reduce the cost of expensive CCVs that were introduced to replace NTVs in Asia. Thailand was the first country to begin using ID regimens to administer CCVs. The Thai Red Cross or '2-2-2-0-2' regimen and the Eight-site or '8-0-4-0-1-1' regimen are two ID regimens currently recommended for use by the WHO, the Thai Red Cross regimen being the most widely used ID vaccination regimen. The updated '2-2-2-0-2' regimen is administered with 0.1 ml doses of vaccine ID over the deltoid region on days 0, 3, 7, and 28. In the '8-0-4-0-1-1' regimen, vaccine is administered ID in a 0.1 ml dose at eight different sites (upper arms, lateral thighs, suprascapular region, and lower quadrant of abdomen) on day 0, another 0.1 ml dose of vaccine at four different sites (each upper arm and each lateral thigh) on day 7, and another 0.1 ml dose of vaccine in the upper arm on days 28 and 90. It is important to note that all of the PEP regimens have been developed with the administration of RIG to provide initial passive immunity.

Second Line of Defense: Establishing Active Adaptive Immunity

Because RABV is strictly neuroinvasive and little viral antigen is present in tissue in the early stages of the disease, the humoral response to viral antigens in the infected host is negligible until later in the course of infection, usually after clinical signs appear, and remains low until the terminal phase of the disease. High levels of antibody appear in serum and in CSF only at death and in cases where illness is naturally or artificially prolonged. In the rare cases of chronic and abortive RABV infections, virus-specific antibodies have been

detected in the serum and CSF, and in the brain of animals. VNA is produced in response to the massive amount of viral antigen (G in particular) that is generated through widespread infection of the CNS and made accessible to the host's reticuloendothelial system.

The critically important cell-mediated immune response to RABV infection is perhaps the most puzzling of the host's total immune response to RABV infection. T-helper lymphocytes, which play an essential role in supporting B-cell production of antibodies, and cytotoxic lymphocytes (CTLs), which function independently in cell-mediated viral clearance, are both key responses in the cell-mediated immunity derived from viral antigens. However, in spite of their importance in viral clearance, T-lymphocytes appear to be suppressed in animals infected by pathogenic 'street' viruses. As a result of virus-induced immunosuppression, the disease increases in severity and mortality rises. The strongest indications that T-lymphocytes play a role in immune protection against RABV infection comes from studies in which athymic (nude) mice died when infected with the attenuated Flury HEP strain that normally causes nonlethal infection of the CNS. Normal mice, similarly infected, show no signs of the disease. Likewise, when normal mice infected with Flury HEP virus are treated with the immunosuppressive agent, cyclophosphamide or antithymocyte serum, the infection becomes as lethal as street virus (mortality in groups of mice increases to 50% and occasionally to as high as 100%). Mice that survive avirulent virus infection develop CTLs, whereas the mice treated with immunosuppressants and mice infected with virulent virus fail to develop CTLs. Further evidence for the protective role of CTLs has come from adoptive transfer experiments in which G-specific CTL clones were observed to protect mice against RABV infection. Since the function of CTLs is to destroy target cells that display virus-induced changes on their surfaces, it is clear that a strong CTL response is essential in mice that survive RABV infection. It is clear from these studies and others that both B- and T-cells play an important role in virus clearance.

Unlike the response to virulent RABV infection, immunization with attenuated live and inactivated RABV vaccines induces humoral and cell-mediated immune responses that develop to functional levels in 7–10 days and persist for a year or more. Vaccine-induced antibody and T-cell-mediated responses in animals and humans, known as adaptive immune responses, are regarded as key and are of paramount importance in the prophylactic protection of animals and humans. Also, acute infections caused by live virulent RABV strains, as well as the less virulent strains, injected into a peripheral site (e.g., the hind leg of an animal), that progress to and within the spinal cord and the brain are accompanied by the production of the inflammatory cytokines IL-1, TNF- α , INF- β , and IL-6, as well as chemokines such as CCL-5 and CXCL-10. This indicates that the nervous system can sense RABV entry and mount a reactive innate, as well as an adaptive immune response. An adaptive innate immune response is helpful in PEP and PET if, as proposed, chemokines and inflammatory cytokines attract lymphocytes that are activated in the periphery. It is to be emphasized that even with a relatively rapid adaptive immune response of 7–10 days, the requirement in PET for the administration of RIG is critical. RIG is the fraction of anti-rabies serum produced in immunized humans (HRIG) or equines (ERIG), which provides immediate passive immunity. It is administered with proven effectiveness over the initial few days and even weeks after RABV exposure in humans. RIG must be administered to humans exposed to RABV as a passive immune treatment in order to provide immediate access to VNAs until the patient's immune system can begin to produce its own antibody. The importance of antibodies in controlling the spread of RABV infections is clear when one considers that antibodies are capable of effectively neutralizing virus that is present in intercellular spaces or in body fluids. Antibodies may bind to virus expressed on the cell surface, allowing complement- or antibody-dependent cellular cytotoxicity to mediate killing of infected cells.

Antibodies, however, are also implicated in an immunopathologic role in regard to the 'early death' phenomenon, which is associated with rabies in animals and possibly humans. If animals have low levels of virus- or vaccine-induced rabies-specific antibody at the time they are challenged with RABV, they frequently die earlier than those without antibodies. In an analogous situation, where humans appear to develop clinical rabies with shorter incubation periods as a result of postexposure immunization, compared with individuals who were exposed to rabies but not immunized, the early death phenomenon may also apply. Inasmuch as the mechanism of early death may resemble the immune cytolysis observed in RABV-infected cells treated with antiserum and complement *in vitro*, the immunopathologic effect of antibody would be to accelerate the pathogenesis of the virus.

The efficacy of postexposure immunization and long-term effects of vaccine-induced prophylaxis against rabies seems also to be linked to the stimulation of a strong CTL response. Induction of CTLs and other effector T-cells during infection with live attenuated RABV vaccine strains and in response to immunization with inactivated virus is consistent with the observation that T-lymphocytes, and CTLs in particular, are essential for protection against a lethal dose of RABV. There is no evidence that early death is associated with rabies-specific T-cells or does any other form of immunopathology appear to be mediated through rabies immune T-cells.

For further information regarding practical approaches toward rabies prevention, including the rationale for PrEP and PEP, treatment of wounds, vaccines and vaccine dosage, booster vaccination, and serologic testing, the reader is referred to the recommendations of the ACIP.

Glossary

Anaplerosis Process that replenishes TCA cycle intermediates that were lost for anabolic purposes.

Autotrophic organism One that manufactures organic compounds from inorganic compounds using energy from sunlight or from chemical reactions; for example, oxidation of H₂S, NH₃, or Fe²⁺.

Carbon catabolite repression (CCR) Process in which glucose or other rapidly metabolizable carbon sources prevent the uptake and/or utilization of other carbon sources.

Catabolite activator protein (CAP) Also known as cAMP receptor protein (CRP). Transcription factor of enteric bacteria that, in complex with cAMP, is required for the transcription of most catabolite-repressed genes.

Catabolite control protein (CcpA) Transcription factor of Firmicutes that, in complex with P-Ser46-HPr, is responsible for repression of most catabolite-controlled genes.

Central metabolism The combined pathways of glycolysis, namely, the Embden–Meyerhof–Parnas pathway, the Entner–Doudoroff pathway, the pentose phosphate pathway, and the TCA cycle. Their role is to generate energy (ATP), to reduce power (NADH and NADPH), and to act as the precursor compounds for the biosynthesis of all other cellular constituents.

Diauxie The process by which bacteria supplied with more than one carbon source uses one carbon source before the others and then induces the enzymes necessary for the use of the second carbon source.

Inducer exclusion Process in which glucose or other rapidly metabolized carbon sources prevent the uptake of alternative sugars and hence prevent the induction of the genes necessary for the metabolism of the alternative sugar. Inducer exclusion is one aspect of CCR.

Phosphotransferase system (PTS) System of proteins for the simultaneous uptake and phosphorylation of sugars.

A phosphate derived from phospho-*enol*-pyruvate (PEP) is passed via a series of proteins and is attached to the sugar as it traverses the internal membrane. Proteins of the PTS are involved in inducer exclusion and catabolite repression in both Gram-positive and Gram-negative organisms.

Phototrophic (or photosynthetic) organism One that manufactures organic compounds using energy from sunlight, carbon dioxide, and water (cf. autotrophic organism).

PTS regulation domain (PRD) A domain subject to phosphorylation by either the EIIB domain of a specific PTS transporter or HPr. It is found in transcriptional activators or antiterminators, mostly in Firmicutes.

Regulon A group of genes possibly dispersed on the bacterial chromosome, but which are controlled by the same factor or signal.

Abbreviations

α-CTD C-terminal domain of the alpha subunit of RNAP

α-NTD N-terminal domain of the alpha subunit of RNAP

ABC ATP-binding cassette

AC Adenylate cyclase

ARI Activating region I

CAP Catabolite activator protein (=CRP)

CCA Carbon catabolite activation

CcpA Catabolite control protein

CCR Carbon catabolite repression

[☆]*Change History*: September 2017. J Plumbridge and J Deutscher updated text, section headings, and Fig. 1 and replaced Fig. 4 with a new figure. April 2019. J. Plumbridge and J. Deutscher included a “Note added in proof” with further updates.

This article is an update of J. Plumbridge, Regulation of Carbon Assimilation in Bacteria, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 375–394.

Crc	Catabolite repression control
cre	Catabolite response element
CRP	cAMP receptor protein (=CAP)
crr	Carbohydrate repression resistant
ED	Entner–Doudoroff pathway
EI	Enzyme I
EMP	Embden–Meyerhof–Parnas pathway
PEP	Phospho- <i>enol</i> -pyruvate
PQQ	Pyrroloquinoline-quinone dependent
PRD	PTS regulation domain
PTS	Phosphotransferase system
RAT	Ribonucleotide antitermination targets
RNAP	RNA polymerase
UAS	Upstream activating site

Defining Statement

Bacteria must adapt to the nutrients available in their environmental niche. One important regulatory mechanism to optimize carbon use is carbon catabolite repression. Different strategies adopted by bacteria to optimize their use of available carbon sources are described.

Introduction

The Need to Regulate

Like all living organisms, bacteria have to adapt to their environment. Their major concern is to find the nutrients that they need to survive. A source of assimilable carbon is a primary requisite and, except for phototrophic (photosynthetic) bacteria or other autotrophs, this means some form of organic carbon compound. The ability of bacteria to use an incredible range of carbon sources is indicative of the equally wide range of habitats where they are found. Their ability to inhabit a particular environment is reflected in the cohort of genes that are present in their genomes for taking up and degrading the variety of compounds likely to be available in a particular location. These range from the nutrient-rich environments of lactic acid bacteria to the low-nutrient aqueous environments frequented by *Caulobacter crescentus* and ocean-dwelling bacteria. There is a rough correlation between genome size and metabolic capacity. Lactic acid bacteria, which are endogenous to food-related habitats, or pathogens and symbionts living in close connection with their host cells, have slimmed down their genomes, whereas bacteria adapted to more diverse or desertlike conditions have retained all their biosynthetic capacities plus diverse catabolic pathways for a wide range of potential nutrients.

Most experimental studies have been performed in the completely artificial environment of the Erlenmeyer flask, supplied with high concentrations of a single carbon source or a defined mix of nutrients during exponential growth. Bacteria in nature will rarely find themselves in a richly supplied medium and, at best, pass between times of relatively high levels of nutrients to a stage when all has been used up and the bacteria must either go searching for a new supply or wait until more food comes their way. This has led to the “feast or famine” concept. In the last decades, attempts have been made to mimic a more natural state by using carbon limitation in chemostats and long-term growth experiments (Ferenci, 2008).

It has long been known that not all carbon sources are equal, and some are certainly more equal than others; that is to say, one carbon source is used preferentially before others. In general, this equates to a rapidly metabolizable carbon source being used first. This observation poses another question of why some carbon sources are used more rapidly than others. The general consensus (dogma) is that uptake is the rate-limiting step. Limitation at the level of uptake could be due to the amount of the transporter available, the activity of the transporter for a specific substrate, or the supply of energy to energize the transport system. However, other intracellular steps, such as the amount or activity of an enzyme needed to metabolize a compound or the supply of an intermediate that is required for its metabolism, for example, ATP or NADH, could be limiting. It is frequently observed that overproduction of one key enzyme within a pathway does not increase flux through the pathway because something else is limiting. Metabolic flux analysis has addressed the problem of flux control during glycolysis, and for *Escherichia coli* the rate of use of ATP, by the anabolic pathways, appeared to be the rate-limiting step. Artificially increasing ATP hydrolysis, by overexpressing the soluble part of ATPase (encoded by *atpAGD*), increased the flux through glycolysis. However, in a similar study on *Lactococcus lactis*, control by ATP consumption was not observed, implying that in this organism there is no excess glycolytic capacity (Koeblmann et al., 2002a,b). Getting the most out of available carbon sources is a major concern of the biotechnological industries, and much effort is being put into identifying and overcoming the bottlenecks in biosynthetic production routes and improving yields from starting compounds, for example, for the synthesis of GlcNAc (Liu et al., 2016; Gu et al., 2017) or scyllo-inositol in *Bacillus subtilis* (Tanaka et al., 2017).

Diauxie and the Hierarchy of Carbon Use

The classic experiment showing the preferential use of one sugar over another is the phenomenon of diauxic growth, as described by Jacques Monod. *E. coli* supplied with a mixture of glucose and lactose completely uses the glucose first, and it then effectively stops growing (lag time) while the genes for uptake and degradation of lactose are induced before the bacteria resume growth, at a slower rate, using lactose as the carbon source.

The ability of glucose to inhibit the use of other carbon sources in enteric bacteria was called the “glucose effect” and is now known to be an aspect of the general phenomenon of carbon catabolite repression (CCR). This is a term that covers a range of physiological phenomena that enable bacteria to make a hierarchical choice between different sources of carbon. CCR exists in all bacteria, but the form it takes varies between different species. Generally, glucose is the preferred carbon source but this is not a universal rule. For example, the nitrogen-fixing *Azotobacter vinelandii* uses acetate or galactose before glucose and in *Pseudomonas putida* succinate produces stronger CCR than glucose (Rojo, 2010). CCR has been most extensively studied in two model organisms: *E. coli* for Gram-negative bacteria and *B. subtilis* for Gram-positive species (Görke and Stülke, 2008). In these two organisms, the molecular mechanisms are quite different, and although they are representative of bacterial species closely related to themselves, it is clear that there are alternative, completely different, mechanisms operational in other bacteria. Studies on carbon control in other microorganisms, particularly those with biotechnological or pharmaceutical applications, such as *Streptomyces coelicolor* or *Corynebacterium glutamicum*, are revealing a very diverse set of mechanisms. Even the dogma of hierarchical choice of nutrients is not sacrosanct because *C. glutamicum* prefers to use several carbon sources simultaneously. Both experimental and theoretical considerations show that, depending on conditions, *E. coli* can use several sugars or other carbon sources simultaneously, following a hierarchy generally reflecting the growth rates of individual compounds, and provided that they are not exerting strong catabolite repression (Aidelberg et al., 2014; Hermesen et al., 2015). Improved techniques of analysis of individual cells have shown that the gene induction response within individual cells to external sugars is not homogeneous and that there can be “all-or-none” and “graded” responses that are possible depending on the carbon source (Afroz et al., 2014; Rao and Koirala, 2014). Similar considerations can explain the existence of so-called bistable states within isogenic bacterial populations (Kotte et al., 2014), and these considerations led to the concept of “microbial bet-hedging,” which posits that a phenotypically mixed population of bacteria might be better prepared to adapt to and survive within rapidly changing environments (Grimbergen et al., 2015).

Global Versus Specific Regulation

The proteins and genes responsible for CCR are the prime examples of global regulators in bacteria. They control a large number of genes in a coordinated manner, albeit with a certain level of flexibility depending on the individual genes under regulation. It has been estimated that 50% of the genes in *E. coli* are regulated by one of the seven global regulators (Martinez-Antonio and Collado-Vides, 2003) and, of these seven, catabolite activator protein (CAP; also called CRP, cAMP receptor protein) is by far the most important with more than 200 direct targets. Expression of catabolite-regulated genes in *E. coli* usually requires transcriptional activation by the cAMP/CAP complex. The magnitude of the activation by cAMP/CAP of different genes varies considerably and depends on the promoter and the sequence and location of the CAP-binding site on the target DNA. The global reduction in cAMP/CAP activation when a preferred carbon source (e.g., glucose in the case of *E. coli*) is present, means that none of the other carbon utilization systems is expressed. However, in the absence of glucose, the bacteria do not want to express their full repertoire of all other carbon utilization operons, which can amount to many hundreds of genes. So, superimposed on the generalized response to catabolite regulation, there are specialized regulatory mechanisms dedicated to individual carbon sources. In the case of the diauxie experiments of Monod, the presence of glucose prevented the expression of genes for most other carbon utilization systems, but when the glucose had been used up, the presence of lactose meant that only the genes of the *lac* operon were expressed and not those for use of other carbon sources like maltose or arabinose.

Subsequent experiments, however, showed that this idea is too simplistic. The bacterial response to changing energy supplies is not just on/off but is more measured. Global transcriptome analysis of RNA from bacteria grown in the presence of different carbon sources, producing a wide range of growth rates from 0.97 h⁻¹ (glucose) to 0.13 h⁻¹ (proline), has shown that, as the quality of the carbon source declines and the growth rate decreases, bacteria gradually upregulate a wide range of genes to broaden their metabolic potential and scavenge for alternate carbon sources (Liu et al., 2005). Similarly, a transcriptome analysis of cells undergoing diauxie showed that a range of stress-related genes (controlled by σ^S , the stationary phase sigma factor, encoded by *rpoS*) and stringent response genes (controlled by ppGpp) are also activated (Traxler et al., 2006). Current model-based approaches of gene expression analysis have shown that both specific (transcription factor) and global (including CAP/cAMP) regulatory mechanisms are active during steady-state conditions but that the global physiological controls are crucial for transitions between steady states (Berthoumieux et al., 2013; Gerosa et al., 2013).

Sensing and Signaling

The general rule is that genes required for use of a particular carbon source are only expressed at a high level when the compound is available to be assimilated. This requires a signal transduction pathway to sense the external presence of the compound and turn on

the expression of the required genes. This type of regulation is nearly always transcriptional, implicating transcription factors acting either positively (activators) or negatively (repressors), of which the classic examples in *E. coli* are the lactose and galactose repressors and the maltose and arabinose activators. A sugar outside the cell enters at a low level, generating a signal that is detected inside the bacteria, indicating the presence of the carbon source outside. The signal is generally a small molecule related to the pathway under control (allolactose, galactose, maltotriose, and arabinose in the four examples listed). The signal starts to induce the genes necessary for the transport of the sugar, thus amplifying the intracellular signal and the level of induction. There are some alternative methods of signaling an available nutrient. Some signaling is due to phosphorylation cascades, as in the case of two-component regulators. Detection of a signal outside the bacteria provokes the autophosphorylation of a histidine sensor kinase, which in turn phosphorylates and activates a second protein, a response regulator, which is generally a positive transcription factor. There are a few examples of two-component systems regulating the use of a carbon supply; for example, the uptake of hexose phosphates in *E. coli* by the UhpT transporter is controlled by the UhpABC-encoded two-component system, but generally this type of regulation is associated with stress responses. In bacteria, the phosphotransferase system (PTS), a major sugar uptake system, is responsible for many signaling phosphorylation reactions (Deutscher et al., 2014a; Galinier and Deutscher, 2017), which are described in the text that follows (see “Catabolite Repression in Gram-Negative Bacteria: *E. coli*” and “Catabolite Repression in Firmicutes: *B. subtilis*” sections). A slight variation to the rule that regulation of sugar use is at the level of transcription initiation is the case of some PTS sugar operons of *B. subtilis*, whose induction is at the level of transcription elongation involving a transcription antitermination mechanism (see “Transcriptional antitermination of PTS operons” section).

These sugar-specific factors all work in collaboration with the global regulators (cAMP/CAP in *E. coli*) so that together there is a combination of positive induction superimposed on relief of catabolite repression to allow the expression of the genes at the required time. The details of each regulated system are unique. Transcription factors, even those belonging to well-described families, all have their own individual characteristics. Common variations are the number and position of operator sites involved and the need for other DNA-binding proteins producing complex nucleoprotein structures in either the activated or the repressed state. For example, repression of both the *gal* and *lac* operons in *E. coli* requires DNA loop formation between Lac or Gal repressors bound to three (in the case of *lac*) or two (in the case of *gal*) operators. In the case of the *galETK* operon, the histone-like protein, HU, is also required for formation of the *gal* repression loop (Kar and Adhya, 2001).

Since the pioneering studies of Jacob and Monod on the *lac* operon in the 1950s and 1960s, people have been dissecting in more and more detail the mechanisms of regulation inherent in the use of numerous carbon sources, especially in *E. coli* and *B. subtilis*, but also in other more exotic bacteria. The 21st century launched the genomic era, which revolutionized the study of bacterial carbon use. The sequences of thousands of bacterial chromosomes allow comparative genomics to (try to) predict what carbon sources are likely to be used and in some cases identify gene functions and potential regulatory mechanisms, for example (Yang et al., 2006; Plata et al., 2012). It should be noted, however, that structural genes for enzymes are much better conserved than either their gene organization or the intergenic regulatory sequences. Regulatory patterns are only conserved in closely related organisms. Adenylate cyclases (AC) and CAP homologues are found in a wide range of bacteria, but the erstwhile paradigm of catabolite repression by cAMP/CAP only exists in the γ -proteobacterial lineage.

In addition to genomic sequencing, the other “-omic” studies of transcriptome (microarrays and RNA sequencing), proteome and metabolome, have allowed studies of the global response of bacteria to a wide range of nutrients, stimuli, and mutations. Exploiting the data from these studies has led to the large advances in the fields of flux analysis and systems biology to understand the flow of metabolites and generalized coordination of cell growth (Kochanowski et al., 2013a; Chubukov et al., 2014). These studies have shown that the number of genes in a regulon, that is, the family of genes coregulated by a transcription factor, is often higher than previously anticipated. Moreover, they have confirmed that the genes of the central carbon pathways in bacteria, the housekeeping genes of glycolysis, pentose-phosphate and TCA cycle are not just constitutively expressed but are also subject to complex regulation. Comparative studies in different bacteria have revealed that, even if the same basic pathways exist, their relative use can be very different from species to species (Fuhrer et al., 2005; Tannler et al., 2008a).

Posttranscriptional Regulation of Carbon Use

Regulation involving sRNA

Although it remains true that the switching on or off of a gene or an operon at the level of transcription initiation remains the most economical method of controlling expression in response to large changes in environmental conditions, like the detection of a new carbon supply, there is increasing evidence of many other layers of regulation that are superimposed to coordinate bacterial cell metabolism. These “posttranscriptional” mechanisms include translational regulation and mRNA degradation and particular control via sRNAs (Görke and Vogel, 2008; Bobrovskyy and Vanderpool, 2013; Bobrovskyy et al., 2015). For example, under conditions of excess glucose-6P (phospho-sugar stress), the sRNA, SgrS, is induced, and by binding in the region of the translational initiation site it inhibits translation of *ptsG*, encoding the major glucose transporter in *E. coli*. This results in the RNase E-dependent degradation of the *ptsG* mRNA (see “The SgrS/SgrT Novel sRNA/small protein pair” section).

The Spot42 sRNA was one of the first sRNAs identified. Initially it was found to be responsible for the discoordinate expression of *galK* in the *galETK* operon, and now microarray analysis has identified numerous carbon-use-related targets. Since these targets are mostly activated by cAMP/CAP, whereas expression of the Spot42 RNA is repressed by cAMP/CAP, this

creates a system for modulating their expression in response to catabolite repression (Beisel and Storz, 2011). On the other hand, expression of the CyaR sRNA is activated by cAMP. Microarrays identified diverse targets that are negatively regulated by CyaR, including outer membrane proteins. These are thus indirectly repressed by cAMP/CAP and represent another manner of tuning carbon metabolism to outside stimuli (De Lay and Gottesman, 2009). The Csr (carbon storage regulator) system includes the CsrA RNA-binding protein and two “decoy” sRNAs: CsrB and CsrC. CsrA was initially implicated in repressing the glycogen synthesis gene and coordinating the shift between glycolytic and gluconeogenesis carbon use. It has now been shown to have multiple roles including in biofilm formation and pathogenicity (Romeo et al., 2013) (see “Other Global Regulators of Carbon Use” section). sRNA seem to play a similarly important role in the carbon metabolism of *B. subtilis* and other Gram-positive bacteria (Mars et al., 2016).

Allosteric regulation

As in the case of transcriptional regulation, controls via sRNAs affect the cellular *levels* of enzymes. In addition, protein modifications (phosphorylation, acetylation) or protein–protein or protein–small-molecule interactions can affect the *activity* of enzymes or regulators (Deutscher et al., 2014a). The last few years have seen significant developments in the techniques of metabolomics, that is, the ability to accurately measure the intracellular concentrations of a large number of metabolites within the cell. Improvements in mass spectrometry resolution and sampling techniques mean that the number of compounds identified and the time taken to identify them have improved considerably (Bennett et al., 2009; Zamboni et al., 2015; de Raad et al., 2016). These have allowed the comparison of the pathways of carbon metabolism under many different conditions. The use of isotope labeling, such as ^{13}C -isotopologue profiling (Eisenreich et al., 2010), has allowed real-time analysis of bacterial cultures undergoing a nutrient or environmental switch (Link et al., 2015).

It has long been known that many of the enzymes of glycolysis are allosteric, that is, their activity changes in response to the binding of a compound at a site other than the active site. Allosteric enzymes, such as phosphofructokinase, have been extensively studied in vitro, but visualizing allosteric effects in vivo are extremely rare. However, the application of rapid sampling metabolomics and advanced mathematical modeling have demonstrated the consequences of an allosteric transition in vivo and have identified potentially new allosteric regulations (Xu et al., 2012; Link et al., 2013). The current consensus of opinion is that transcriptional regulation allows (long-term) adaption to changing environmental conditions, whereas the posttranslational and allosteric regulations are (short-term) fixes to maintain flux balance (Kochanowski et al., 2015). Together, the cell has integrated these multiple controls to allow balanced growth. A major aim of the systems biology approach is to describe this complex regulation in terms of mathematical models of glycolysis or even cellular metabolism (O’Brien et al., 2013; Link et al., 2014; Kremling et al., 2015; Huan et al., 2017).

Carbon Assimilation Pathways: Central Carbon Metabolism

Carbon assimilation can be divided into two levels: peripheral and central. The peripheral steps transform diverse and varied carbon sources into phosphorylated intermediates, which can then be channeled into one of the major routes for the dissimilation of carbon. These central routes are the three interconnecting pathways of glycolysis (EMP = Embden–Meyerhof–Parnas pathway), the Entner–Doudoroff (ED) pathway, and the pentose phosphate pathway, which all feed carbon into the TCA (Krebs) cycle (Fig. 1 and Table 1). There are, of course, exceptions, for example, lactic acid bacteria, which do not contain a complete TCA cycle, can normally only use carbohydrates via fermentation. The enzymes of central metabolism are historically some of the best studied. Together, these reactions generate energy (ATP), reducing power (NADH and NADPH), and, directly or indirectly, the precursor molecules for all the biosynthetic reactions. The 13 intermediates that are drawn away from the central pathways of carbon metabolism are glucose-6P (to be used to make sugar nucleotides), fructose-6P (for amino sugars), pentose phosphates (for various vitamins and cofactors, purine and pyrimidine nucleotides, histidine, and tryptophan), sedoheptulose phosphate (for heptoses in lipopolysaccharides), erythrose phosphate (for aromatic amino acids and some vitamins and cofactors), dihydroxyacetone phosphate (for nicotinamide coenzymes and phospholipids), 3-phosphoglycerate (for serine family amino acids, tryptophan, and purine nucleotides), phospho-*enol*-pyruvate (for various vitamins, cofactors, aromatic amino acids and peptidoglycan), pyruvate (pyruvate family amino acids), acetyl-CoA (for fatty acids, peptidoglycan, and leucine), oxaloacetate (aspartate family amino acids and pyrimidine nicotinamide coenzymes), 2-ketoglutarate (glutamate family amino acids, polyamines, and heme derivatives), and succinyl-CoA (for lysine family amino acids and heme derivatives).

Glycolysis, Entner–Doudoroff, and Pentose Phosphate Pathways

In glycolysis, six-carbon sugars are split into three-carbon compounds and then are converted into PEP (phospho-*enol*-pyruvate), pyruvate, and acetyl-CoA, generating ATP and NADH (Fig. 1). Glycolysis (EMP pathway) was considered the trunk route of sugar metabolism because it is the predominate route in the model organisms *E. coli* and *B. subtilis*. However, the relative importance of the EMP and ED pathways and the oxidative branch of the pentose phosphate pathway varies in different organisms. Quantitation of intracellular fluxes during growth on glucose of seven bacterial species showed that the relative use of the different pathways of central metabolism varied considerably (Fuhrer et al., 2005). In the ED route, glucose is converted to gluconate-6P using the

Fig. 1 Pathways of central carbon metabolism. Routes of glucose use via glycolysis (shaded yellow), Entner–Doudoroff (blue), pentose phosphate pathway (green), and TCA cycle (pink) are shown. Reactions specific to gluconeogenesis are shown with blue arrows. The enzymes encoded by the different genes are listed in Table 1. The pathways shown are those of *E. coli*, and certain specific differences existing in *B. subtilis* are indicated in Table 1. The *gapB* gene for gluconeogenic glyceraldehyde-3P dehydrogenase is only present in *B. subtilis*. The *ppc* gene does not exist in *B. subtilis*, anaplerosis occurs via *pycA*, encoding pyruvate carboxylase, which forms oxaloacetate from pyruvate.

Table 1 The genes and enzymes of central carbon metabolism

Gene name		
<i>E. coli</i>	<i>B. subtilis</i>	Enzyme
<i>Glycolysis</i>		
<i>glk</i>	<i>glcK</i>	Glucokinase
<i>pgi</i>		Phosphoglucose isomerase
<i>pfk</i>	<i>pfkA</i>	Phosphofructose kinase
<i>fbaA</i>		Fructose-1,6 aldolase
<i>tpi</i>		Triose phosphate isomerase
<i>gapA</i>		Glyceraldehyde-3P dehydrogenase
<i>pgk</i>		Phosphoglycerate kinase
<i>gpmA</i>	<i>pgm</i>	Phosphoglycerate mutase
<i>eno</i>		Enolase
<i>pyk</i>		Pyruvate kinase
<i>aceEF lpd</i>	<i>pdhABCD</i>	Pyruvate dehydrogenase
<i>Entner-Doudoroff pathway</i>		
<i>gcd</i>	—	Glucose dehydrogenase (PQQ ^a)
<i>gntK</i>		Gluconokinase
<i>zwf</i>		Glucose-6P dehydrogenase
<i>pgl (ybhE)</i>	<i>ykjB^b</i>	Phosphogluconolactonase
<i>edd</i>	—	Phosphogluconate dehydratase
<i>eda</i>	<i>(kdgA)^c</i>	2-Keto-3-deoxygluconate-6P aldolase
<i>Pentose phosphate pathway</i>		
<i>gnd</i>	<i>gndA (yqjI)^d</i>	Gluconate-6P dehydrogenase
<i>rpe</i>		Ribulose-5P epimerase
<i>rpi</i>	<i>ywlF^e</i>	Ribulose-5P isomerase
<i>tkt</i>		Transketolase
<i>tal</i>	<i>ywjH^e</i>	Transaldolase
<i>TCA cycle and glyoxylate shunt</i>		
<i>ppc</i>	—	PEP carboxylase
—	<i>pycA</i>	Pyruvate carboxylase
<i>gltA</i>	<i>citZ (citA)</i>	Citrate synthase
<i>acnB</i>	<i>citB</i>	Aconitase
<i>icd</i>	<i>citC</i>	Isocitrate dehydrogenase
<i>sucAB lpd</i>	<i>odhABpdhD</i>	2-Ketoglutarate dehydrogenase
<i>sucCD</i>		Succinyl-CoA synthetase (succinate thiokinase)
<i>sdnCDAB</i>	<i>sdhCAB</i>	Succinate dehydrogenase
<i>fumA</i>	<i>citG</i>	Fumarase
<i>mdh</i>	<i>citH</i>	Malate dehydrogenase
<i>maeB maeA (sfcA)</i>	<i>ytsJ^f</i>	Malic enzyme
<i>aceA</i>	—	Isocitrate lyase
<i>aceB</i>	—	Malate synthase
<i>aceK</i>	—	Isocitrate dehydrogenase kinase/phosphatase
<i>Gluconeogenesis and growth on acetate</i>		
<i>pps</i>		PEP synthetase
<i>fbp</i>		Fructose biphosphatase
<i>pck</i>	<i>pckA</i>	PEP carboxykinase
<i>acs</i>	<i>acsA</i>	Acetyl-CoA synthetase
—	<i>gapB</i>	Glyceraldehyde-3P dehydrogenase
<i>Overflow metabolism</i>		
<i>pta</i>		Phosphotransacetylase
<i>ack</i>	<i>ackA</i>	Acetate kinase
<i>ldhA</i>		Lactate dehydrogenase
<i>adhE</i>	<i>adhA</i>	Alcohol dehydrogenase

The gene names for the enzymes in *E. coli* are given in the first column. When different, the *B. subtilis* name is given in the second column. A *dash* indicates that the enzyme is not found in either of the bacteria. Isozymes exist for many genes, which are active under different conditions, for example, aerobic, anaerobic, oxidative stress, stationary phase, etc. The name of the gene encoding the predominant enzyme active during aerobic exponential growth is given.

^aPQQ, Pyrroloquinoline-quinone dependent.

^bPlata et al., 2012.

^cPart of the *kdgRKAT* operon.

^dOther paralogues (GntZ, Yqec) exist, but YqjI (renamed GndA) is the major enzyme required for growth on glucose and gluconate (Zamoni et al., 2004).

^eIndicates putative identification based on homology.

^fYtsJ (NADPH-dependent) is required for growth on malate. Three other paralogous genes (NADH-dependent) encoding malic enzymes also exist in *B. subtilis* *maeA*, *malS*, *mleA* (Lerondel et al., 2006).

enzymes Glc6P dehydrogenase (*zwf*) and phosphoglucanase (*pgl*) and then dehydrated to 2-keto-3-deoxygluconate (*edd*), which is cleaved into glyceraldehyde-3P and pyruvate (*eda*). In *E. coli*, sugar acids such as gluconate and galacturonate, derived from mammalian and plant tissues, are processed via the ED pathway. The ED route is absent in *B. subtilis* but in many other bacteria it is the major route for glucose metabolism. In some bacteria, such as the xenobiotic-degrading *Pseudomonades*, the ethanol-producing *Zymomonas mobilis*, and the human pathogen *Neisseria meningitidis*, there is no *pfk* gene for phosphofructose kinase, a key enzyme of glycolysis, implying that glucose is processed through the ED pathway. It has been hypothesized, based on phylogenetic analysis, that the ED route is the original route to degrade glucose (Romano and Conway, 1996; Flamholz et al., 2013). The oxidative part of the pentose phosphate pathway uses the same first two enzymes (*zwf* and *pgl*) as the ED route does in forming gluconate-6P, which is then decarboxylated to ribulose-5P, generating NADPH. A series of transketolase and transaldolase reactions produces sugar phosphate precursors (for the biosynthesis of aromatic amino acids, vitamins, and nucleotides) and ultimately glyceraldehyde-3P and fructose-6P (Fig. 1). A recent metabolic flux analysis of glucose use by *P. putida* has confirmed the dominance of the ED route but also has shown that *P. putida* processes 10% of glucose via the pentose-phosphate route and that a significant part of the glyceraldehyde-3P generated is recycled back to hexose-P (gluconeogenesis) via the upper part of the EMP pathway (the EDMP route). This is proposed to facilitate maintaining a correct NADPH/NADP balance (Nikel et al., 2015) (see “Balancing the Redox Potential, NADPH/NADH” section).

Glycolysis and Gluconeogenesis

During rapid growth on glycolytic sugars such as glucose, *E. coli* or *B. subtilis* generate most of the energy they need by substrate-level phosphorylation. A part of the carbon flux is directed into the TCA cycle to generate 2-ketoglutarate and oxaloacetate (anaplerosis), while the excess carbon is excreted as acetate (a process normally called *overflow metabolism*). When all the glucose is used, the acetate can be reabsorbed and used to generate acetyl-CoA. This has been called the “acetate switch,” when the bacteria switches its enzymatic machinery from excreting acetate to using acetate for growth (Wolfe, 2005). Acetate and other carbon sources that generate acetyl-CoA feed into the TCA cycle so that for bacteria growing on acetate or dicarboxylic acids, the TCA cycle is used to generate energy. A part of the carbon supply must return backward up the glycolysis pathway, in the process called gluconeogenesis, to produce the sugar phosphates required for the synthesis of sugar nucleotides and other precursors to cell-wall and membrane components (El-Mansi et al., 2006).

The majority of the reactions of glycolysis are reversible, but some are irreversible, and specialized enzymes exist to catalyze the reverse gluconeogenic reactions (Fig. 1, blue arrows). Phosphofructokinase (*pfk*) is a classic allosteric enzyme, inhibited by PEP and activated by nucleoside diphosphates (ADP), thus signaling the need for more or less energy generation. Fructose bisphosphatase (*fbp*) performs the reverse reaction; it is inhibited by AMP, activated by PEP, and is active during growth on gluconeogenic carbon sources. Other enzyme pairs performing reverse reactions are pyruvate kinase (*pyk*) generating pyruvate in glycolysis and PEP synthetase (*pps*) synthesizing PEP during gluconeogenesis. In *B. subtilis*, the glyceraldehyde-3P dehydrogenase reaction is also catalyzed by two enzymes, encoded by *gapA*, using NAD as the cofactor, for the glycolytic direction and *gapB* (cofactor NADP) for the gluconeogenic step (Fillinger et al., 2000). In *E. coli*, the *gapA* enzyme functions in both directions. A gene for a highly homologous enzyme exists in *E. coli* and was initially suspected to be another phosphorylating glyceraldehyde-3P dehydrogenase because it is located in an operon with two other glycolytic enzymes, *pyk* and *fbaA*. However, it was shown to be a nonphosphorylating erythrose-4P dehydrogenase (*epd*), using NADP as reductant, and to be part of the biosynthetic pathway toward chorismate.

In both *E. coli* and *B. subtilis*, control mechanisms exist to direct the carbon flow in the glycolytic or gluconeogenic direction. In *B. subtilis*, the genes for the lower steps of glycolysis *gapA*, *pgk*, *tpi*, *pgm*, *eno* are arranged in an operon controlled by the product of the first gene of the operon, *cggR* (central glycolytic genes repressor). Transcriptome analysis suggested that CggR has only one target and is a dedicated regulator of the *gapA* operon. Its primary inducer is Fru1,6P (Doan and Aymerich, 2003). The *B. subtilis* *gapA* operon is also controlled by CcpA, the global catabolite regulator in Gram-positive bacteria (see “Catabolite Repression and Regulation by CcpA and the *cre* Element” section). The expression of the *B. subtilis* genes specific for gluconeogenesis, *gapB*, and *pckA*, is very low in the presence of glucose but is high during growth on succinate. Repression is due to the DNA-binding protein, CcpN (catabolite control protein of gluconeogenic genes). GapA is also regulated indirectly by CcpN under gluconeogenic conditions. The dual function sRNA, SR1, encodes a small peptide, SR1P, which binds the GapA protein and results in a stabilization of the *gapA* mRNA by an as-yet unknown mechanism. The expression of the SR1 RNA is repressed by CcpN, and so SR1P is only active under gluconeogenic conditions (Gimpel and Brantl, 2016). The loss of *ccpN* impairs growth on glucose since the high levels of PEP carboxykinase (PckA) provoke a futile cycle through pyruvate kinase (Pyk) and pyruvate carboxylase (PycA) (Tannler et al., 2008b).

In *E. coli*, the expression of several genes of glycolysis has been shown to increase during growth on glucose, for example, *gapA*, *pgk*, and *fbaA*. The FruR repressor of the fructose PTS, in addition to repressing the *fruBKA* operon 20-fold, more weakly represses the *epd pgk fbaA* operon and other catabolic genes such as *pfk*, *edd*, *eda*, and *ptsH* (part of the PTS, see “The Bacterial Phosphotransferase System” section). FruR also acts as an activator of the *pps* gene (encoding PEP synthetase), some other genes of gluconeogenesis (*pckA*, *fbp*), and the TCA cycle genes (*aceBA*, *icd*). Genomic selex experiments have further increased the number of binding sites (Shimada et al., 2011b). The binding of FruR is inhibited by fructose phosphates, especially Fru1P, but also Fru1,6P, which signals the activity of the glycolytic pathway (Kochanowski et al., 2013b). FruR thus plays a pleiotropic role in directing the carbon flow in response to metabolic signals, and it was renamed Cra (catabolite repressor activator) to reflect

this function. Allosteric regulation also plays a role in directing the flux by the opposing reactions of phosphofructokinase (*pfk*), inhibited by PEP and fructose 1,6-bisphosphatase (*fbp*), activated by PEP. As mentioned earlier, the extensive data generated by high-throughput metabolomics and transcriptomics studies are providing compelling evidence for the importance of these and other posttranslational regulatory mechanisms in maintaining a balanced microbial metabolism (Chubukov et al., 2014; Kochanowski et al., 2015).

The PEP–Pyruvate–Oxaloacetate Node

As in the case of the glycolytic pathway, different sets of enzymes control the direction of the carbon flow between glycolysis and the TCA cycle, which has been called the PEP–pyruvate–oxaloacetate node (Sauer and Eikmanns, 2005). PEP carboxylase (*ppc*) catalyzes the anaplerotic formation of oxaloacetate from PEP and carbonate, whereas PEP carboxykinase (*pck*) carries out the reverse reaction, conversion of oxaloacetate to PEP (Fig. 1). Bacteria with *ppc* mutants require a TCA cycle intermediate (succinate) for growth on sugars to replenish the TCA cycle. PEP carboxylase is a tetrameric allosteric enzyme with many effectors including acetyl-CoA, Fru1,6P, GTP, and long-chain fatty acids (positive), and aspartate and malate (negative). *B. subtilis* does not possess a PEP carboxylase but replenishes the TCA cycle from glycolysis by forming oxaloacetate using pyruvate carboxylase (*pycA*). Pyruvate carboxylase is activated by acetyl-CoA. An exchange between TCA cycle and glycolysis can also occur at the level of pyruvate and malate, catalyzed by so-called malic enzymes, of which several isozymes exist: two in *E. coli* and four in *B. subtilis*. They differ in their cofactor requirements, NAD or NADP. In *E. coli*, both enzymes are active during growth on dicarboxylic acids. In *B. subtilis*, the NADP-linked enzyme (YtsJ) is particularly required for growth on malate (Lerondel et al., 2006). This is most likely related to maintaining the correct NADPH balance. The expression of the operon for the pyruvate dehydrogenase complex (*aceEFHpd*), which transforms pyruvate into acetyl-CoA, is repressed by the pyruvate-sensing repressor, PdhR, a GntR family repressor. PdhR also controls some genes of the respiratory electron transfer system in *E. coli* (Ogasawara et al., 2007), whereas in *B. subtilis*, it is the stringent control mechanism dependent on the ATP/GTP ratio that controls expression of the *pdhABCD* operon, as well as several other glycolytic enzymes (Tojo et al., 2010).

The TCA Cycle and Glyoxylate Shunt

The TCA cycle completes the oxidation of acetyl-CoA produced by glycolysis and provides intermediates for biosynthesis of aspartate, glutamate, and their derivatives. In fact, the TCA cycle rarely runs as a cycle but mostly as two arms producing succinyl-CoA and 2-ketoglutarate from oxaloacetate. During growth on acetate or fatty acids, it runs as two cycles including the glyoxylate shunt (El-Mansi et al., 2006).

The glyoxylate shunt represents a bifurcation of the pool of isocitrate directly toward malate and succinate rather than via 2-ketoglutarate, because the latter route involves two irreversible decarboxylations and hence depletion of the TCA intermediates (Fig. 1). The direction of carbon flow from isocitrate to glyoxylate or to 2-ketoglutarate is decided by the relative activities of isocitrate dehydrogenase (*icd*) and isocitrate lyase (*aceA*). The activity of isocitrate dehydrogenase is strongly downregulated by reversible phosphorylation carried out by the Icd kinase/phosphatase enzyme (IcdK/P), encoded by *aceK*, which was the first ATP-dependent protein kinase identified in bacteria (Cozzone and El-Mansi, 2005). This is the third gene of the inducible *aceBAK* operon, where *aceB* and *aceA* encode the two enzymes of the glyoxylate shunt. All three genes are induced by growth on acetate and repressed by growth on glucose, coordinating a simultaneous decrease in Icd activity and an increase in the glyoxylate shunt or vice versa. A specialized repressor, IclR, whose inducing signal appears to be PEP rather than acetate, controls the operon (Molina-Henares et al., 2006).

The genes of the TCA cycle are controlled by several global regulatory circuits. They are subject to CCR, repressed during growth on glucose, and their expression is dependent on the cAMP/CAP complex in *E. coli* (see “cAMP/CAP Regulation of Transcription Initiation” section). Isozymes for several of the enzymes exist and are subject to different regulations, for example, *fumA* and *acnB* encode the major aerobic fumarase and aconitase activities, whereas *fumC* and *acnA* are expressed under conditions of oxidative or iron stress from an *rpoS*-dependent promoter [*rpoS* encodes σ^S (σ^{38}), the stationary phase/stress-related sigma factor]. Similarly, there are two genes for transketolase; *tktA*, encoding the major isozyme in exponential growth, is repressed in stationary phase when *tktB* is induced. RpoS is implicated in both regulations. The ArcA/ArcB redox-sensing two-component system is responsible for the repression of the TCA cycle genes in anaerobic and microaerobic conditions, but mutations in *arcA* also increase the flux through the TCA cycle during aerobic growth on glucose (Perrenoud and Sauer, 2005).

Succinate dehydrogenase (*sdhCDAB*) is the only membrane-bound member of the TCA cycle and produces a reduced quinone to be used by the respiratory chain. It contains a $[4\text{Fe-4S}]^{2+}$ cluster. Aconitase (*acnA* and *B*) and fumarase (*fumA* and *B*) are also Fe-S enzymes. The Fur protein (iron-specific repressor) was known to positively control the expression of all three enzymes such that *fur* mutants do not grow on succinate. The explanation for this unexpected behavior came with the discovery of the RhyB sRNA. Synthesis of the RhyB RNA is under negative control by Fur so that it is only synthesized when intracellular iron is low. The sRNA, by binding to the *sdhCD* mRNA, initiates RNase E-dependent degradation of the *sdh* mRNA, thus lowering the intracellular content of succinate dehydrogenase (and other nonessential iron proteins) and liberating iron when iron is scarce (Massé et al., 2007). In addition, scarcity of iron is thought to destroy the Fe-S clusters in aconitases. Apo-aconitases, from both bacteria and vertebrates, are mRNA-binding proteins and have been shown to repress

the translation of their own mRNA, thus constituting a double regulation to conserve precious iron supplies (Hantke, 2002). A similar iron-sparing response is found in *B. subtilis*, where Fur represses expression of a sRNA, FrsA, with global effects on TCA cycle function (Smaldone et al., 2012).

In *B. subtilis*, CcpC, a LysR-type regulator, represses the *citZCH* operon (encoding citrate synthase, isocitrate dehydrogenase, and malate dehydrogenase) and *citB* (aconitase) and its own gene (Sonenshein, 2007). The genes of the glyoxylate shunt are missing in *B. subtilis* and in some related species. These bacteria cannot grow on acetate as the sole carbon source. Modified TCA cycles are also found in some other bacteria, such as the γ -aminobutyric acid shunt in the cyanobacteria, *Synechocystis* (Xiong et al., 2014).

Balancing the Redox Potential, NADPH/NADH

A general rule is that catabolic enzymes are coupled to NAD reduction, whereas reactions forming part of anabolic pathways use NADP. Thus the *B. subtilis* GapA enzyme uses NAD while the gluconeogenic enzyme, GapB, uses NADP. The major routes for generating the anabolic reductant NADPH were thought to be via the pentose phosphate pathway and isocitrate dehydrogenase, but in *E. coli*, a membrane-bound proton-translocating transhydrogenase (PntAB) accounts for at least one-third of the cellular NADPH generated from NADH during growth on glucose. A second soluble transhydrogenase (UdhA) seems dedicated to the reverse reaction, generating NADH from NADPH under conditions when NADPH is high (growth on acetate or on sugars metabolized via the pentose phosphate pathway). The expression and/or activity of these enzymes must be carefully controlled to eliminate a futile cycle dissipating NADPH (Haverkorn van Rijsewijk et al., 2016). As the two enzymes have only been detected in enterobacteria, alternative mechanisms must exist in other bacteria to balance their redox potential. In *B. subtilis*, two transhydrogenation cycles, constituted by NADH- and NADPH-dependent isozymes (GapA, GapB and Malic enzymes, MalS, YtsJ), could be responsible for redox balancing (Ruhl et al., 2012).

Uptake of Carbon Sources From the Medium

Sugar-specific utilization operons generally encode two types of enzymes: those involved in the transport of (usually) hydrophilic carbohydrates across the inner membrane and those encoding the enzymes that transform the more exotic starting materials into one of the compounds of the central carbon degradation pathway. For some (larger) carbon sources, a specific outer membrane porin is also required (e.g., LamB for maltose and maltooligosaccharides, or ChiP for chitobiose and chitotriose). The transporters belong to many protein families and are of many types, including H^+ symporters (e.g., LacY where lactose uptake is associated with proton uptake), ATP-binding cassette (ABC)-type transporters (e.g., MalFGK for maltose uptake), and facilitated diffusion (e.g., GlpF, for glycerol uptake). These systems transport the sugars unchanged so that inside the cell they must be phosphorylated by specific kinases.

Another important route is the phosphotransferase system (PTS), which is widely distributed in bacteria. In this group translocation mechanism, sugar transport across the inner membrane is associated with the concomitant phosphorylation of the sugar as it enters the cytoplasm. The phosphate is derived from PEP and passes via a protein phosphorylation cascade to the incoming sugar (Fig. 2). The proteins of the phosphotransferase system are intimately involved in CCR in both Gram-positive and Gram-negative bacteria, although the mechanisms of their action are fundamentally different. Thus we will first describe the PTS as a sugar transporter and then deal with CCR in Gram-negative and in Gram-positive bacteria (Deutscher et al., 2006). In many cases, the transport proteins are intrinsic parts of the machinery for the regulation of their own expression (Vastermark and Saier Jr., 2014), as in the case of PtsG by Mlc in *E. coli*, as discussed later.

Fig. 2 The glucose PTS in *Escherichia coli*. The phosphate from PEP is passed via a series of cytoplasmic proteins EI (*ptsI*), HPr (*ptsH*), and EIIA^{Glc} (*crr*) to the glucose-specific transporter EIIB^{Glc} (*ptsG*). Passage of glucose across the membrane via the EIIC^{Glc} domain results in its simultaneous phosphorylation by EIIB^{Glc} to give cytoplasmic Glc6P.

The Bacterial Phosphotransferase System

The basic PTS consists of two cytoplasmic proteins called Enzyme I (EI, gene *ptsI*) and HPr (*ptsH*) that are common to nearly all sugars and which pass a phosphate derived from PEP to the sugar-specific transporters, called Enzymes II (EII) (Fig. 2). The EIIs are multidomain proteins where the three domains, EIIA, EIIB, and EIIC, can be found on one, two, three, or, occasionally, four polypeptide chains. EIIA and EIIB are soluble cytoplasmic proteins, whereas EIIC is an integral membrane protein that serves as the passage for the sugar through the membrane.

EI autophosphorylates on a histidine residue and then passes the phosphate to the small protein HPr. HPr distributes phosphates to the EIIA domain of any of the sugar-specific EII transporters within the cell. From EIIA, the phosphate is transferred to EIIB, another soluble domain, but this one is associated with the cytoplasmic side of the inner membrane. From EIIB, the phosphate is transferred to the sugar after it has been transported by the EIIC domain across the cytoplasmic membrane by a so-called “elevator” mechanism (McCoy et al., 2016). An alternative “rigid body rotation” mechanism has been proposed for the ascorbate PTS transporter (Luo et al., 2015). The phosphate is carried by a histidine residue in EI, HPr, and EIIA but usually by a cysteine in most EIIB domains. In the resting state, that is, in the absence of a PTS sugar, the PTS proteins are predominately phosphorylated. It should be noted that these phosphate bonds are relatively labile because they are of high and similar-standard free energies, so that the phosphates can be easily passed between different EIIs via the HPr protein.

For the glucose PTS of *E. coli* (Fig. 2), EIIC^{Glc} and EIIB^{Glc} are present on the same polypeptide, encoded by the gene *ptsG*. The EIIA^{Glc} protein is a separate polypeptide, encoded by the gene *crr* (for carbohydrate repression resistant), a name that reflects the primordial role of EIIA^{Glc} in CCR in *E. coli* (see “Catabolite Repression in Gram-Negative Bacteria: *E. coli*” section). In fact, the gene *crr* is part of the *ptsH/crr* operon, encoding the common components of the PTS, whereas *ptsG* is expressed as a single gene elsewhere on the chromosome. The PTS proteins are modular proteins par excellence. The structural genes can be recognized in bacterial genomes by homology-scoring programs, and the EIIs have been divided into several subfamilies, but the arrangement of their domains both within the polypeptides and at the genetic level can vary enormously (Barabote and Saier, 2005). For example, in *E. coli*, the *nagE* gene (with domain order EIICBA^{Nag}) encodes the N-acetylglucosamine (GlcNAc) transporter whereas the homologous β -glucoside transporter, encoded by *bglF*, has the domains arranged as EIIBCA^{Bgl}. The fructose PTS in *E. coli* does not use HPr but has a specialized fusion protein, FPr, including an HPr domain and an EIIA^{Fru} domain. Other unusual fusion proteins exist between both PTS and non-PTS domains, as in the nontransporting dihydroxyacetone kinase system (Gutknecht et al., 2001). Although PTS proteins can be easily identified by sequence homology, it is not usually obvious to predict their sugar substrates. A ground-breaking multiplex mutagenesis protocol (MUGENT) in *Vibrio cholerae* generated a strain lacking 13 PTS operons and enabled assignment of transported sugars to individual transporters (Hayes et al., 2017). The genes for the EII transporter are often associated in operons with genes encoding the enzymes required for further metabolism of their substrate and the transcription factor controlling their expression.

Catabolite Repression in Gram-Negative Bacteria: *E. coli*

The key molecule in CCR in *E. coli* is the EIIA^{Glc} protein. At least two regulatory circuits are in action during CCR by glucose. First, glucose reduces the concentration of cAMP/CAP and so decreases the transcription of target genes, and second, it causes inducer exclusion by preventing the uptake of other carbon sources, and hence prevents induction of the genes required for their metabolism (Deutscher et al., 2006). Both activities depend on EIIA^{Glc}, but their relative contributions to CCR have been the subject of much debate (e.g., Inada et al., 1996; Crasnier-Mednansky, 2008; Görke and Stülke, 2008). There have been many attempts to produce mathematical models of CCR in *E. coli* (e.g., Kremling et al., 2015).

Inducer Exclusion

Mutations in EI or HPr prevent the use of both PTS and non-PTS carbohydrates. Mutations called *crr* (carbohydrate repression resistant) were isolated as suppressors, which restored growth on a range of non-PTS sugars. The *crr* gene, in which the suppressors were mapped, encodes the EIIA component of the glucose PTS. As such, it can exist in two forms: phosphorylated and nonphosphorylated. These two forms were shown to have complementary roles in CCR. The nonphosphorylated form of EIIA, the form expected to predominate when the bacteria are growing on glucose, was shown to interact with and inhibit the activity of numerous transport systems for non-PTS sugars such as lactose, melibiose, raffinose, maltose, and also glycerol kinase (Fig. 3). Inhibition of the basal level of these transporters in the bacteria is responsible for the phenomenon of “inducer exclusion.” Inhibiting the activity of the transporters for different carbon sources prevents the uptake of these alternative substrates and the induction of the genes required for their transport and metabolism. It has been reported that EIIA^{Glc} interacts strongly with transporters only when their specific substrates are present, thus preventing the wasteful sequestration of EIIA^{Glc} to unused transporters. The interaction between EIIA^{Glc} and many of its targets has been demonstrated in vitro. The structures of EIIA^{Glc} in complex with GlpK and MalK (Chen et al., 2013) have been determined. On the other hand, a novel interaction involving dephosphorylated HPr (rather than EIIA^{Glc}) and the mannitol repressor, MtlR, determines the preference of glucose over mannitol (another PTS sugar) in *E. coli* (Choe et al., 2017).

Fig. 3 Carbon catabolite repression in enteric bacteria: *E. coli*. Transport of glucose by the PTS and EII^{CB}^{Glc} (P_{ts}G) produces predominately unphosphorylated EIIA^{Glc}. The nonphosphorylated form of EIIA^{Glc} leads to inducer exclusion because it inhibits the transport activity of non-PTS transporters like LacY and MalE/FK and the glycerol kinase enzyme, GlpK. In the absence of glucose, EIIA^{Glc} is mostly phosphorylated and in this form it allosterically activates the enzyme AC, thus increasing the concentration of cAMP, which forms a complex with CAP. Higher concentrations of cAMP/CAP allow RNA polymerase to bind and transcribe genes for use of alternative carbon sources, in the presence of their specific inducing signal.

Activation of AC

EIIA^{Glc} is also largely implicated in changing the functional concentration of the global activator cAMP/CAP. When available glucose is exhausted, EIIA^{Glc} becomes predominately phosphorylated and cAMP concentrations increase manyfold. This increase has been shown to be in the majority due to an increase in the activity of the enzyme adenylate cyclase (AC, encoded by the gene *cya*). Phosphorylated EIIA^{Glc} stimulates the enzymatic activity of AC 50-fold (Fig. 3). Deletion of the 48C-terminal amino acids from AC prevented this allosteric activation of cyclase activity without affecting the intrinsic basal activity. A small transcriptional effect of EIIA^{Glc}-P on *cya* gene expression has been observed (fourfold), but the major regulation is via the activity of the enzyme. Although the *in vivo* evidence was strong, it was only much later that the stimulation of AC activity by purified EIIA^{Glc} could be demonstrated *in vitro*. It required the addition of a crude *E. coli* extract, indicating that some other, so-far unidentified, factor is also required (Park et al., 2006). More recently, 2-ketoglutarate (2KG) and α -ketoacids in general have been implicated in inhibiting AC *in vivo*. Since 2KG is a key compound for amino acid biosynthesis and an indicator of the nitrogen status of bacteria, this important observation provides a way to coordinate carbon use with both the carbon and nitrogen requirements of the cell's proteome (in particular the ribosomal translational machinery) rather than just to the growth rate or carbon supply (You et al., 2013). This hypothesis led to the idea that α -ketoacids are the key catabolites linking CCR and carbon and nitrogen availability (Rabinowitz and Silhavy, 2013).

It has long been known that glucose is not the only sugar that produces catabolite repression in *E. coli*. Growth on other PTS sugars producing fast growth (e.g., *N*-acetylglucosamine or mannitol) also provokes dephosphorylation of EIIA^{Glc} via the reequilibration of phosphates between the different PTS components. In addition, certain non-PTS sugars, including glucose-6P, gluconate, and lactose, can exert repression on bacteria growing on carbon sources that are not as good (Hogema et al., 1997). The addition of these compounds to bacteria growing on lactate affects cAMP/CAP levels and provokes at least a partial dephosphorylation of EIIA^{Glc}. The level of dephosphorylation of EIIA^{Glc} seemed to correlate with the decrease in the PEP/pyruvate ratio, implying that products from the far end of the glycolysis route are involved in the sensing. It remains to be determined how transport of non-PTS sugars affects the PEP/pyruvate ratio (Hogema et al., 1998; Bettenbrock et al., 2007).

The *crp* and *cya* genes are also subject to multiple levels of regulation. *Crp* is autoregulated by cAMP/CAP, both negatively (at physiologically relevant cAMP concentrations), and positively (at very high concentrations), whereas *cya* is repressed by cAMP/CAP. How these controls are integrated with the EIIA^{Glc} regulation and whether other mechanisms are also implicated is not known. Although under extensive study since the discovery of cAMP in the 1960s, the molecular mechanisms governing the physiological control of cAMP/CAP levels inside the cell are still far from clear. Despite the presence of two cAMP phosphodiesterases, cytoplasmic CpdA and periplasmic CpdB, the majority of the cAMP synthesized by *E. coli* is found in the external medium. There are other unanswered questions. For example, why does Glc6P produce much stronger levels of repression than glucose (Hogema et al., 1997)?

cAMP/CAP Regulation of Transcription Initiation

Despite our still incomplete understanding concerning the physiology of cAMP/CAP, the molecular mechanisms of how cAMP/CAP activates transcription by RNA polymerase have been described in exquisite detail. CAP is undoubtedly the best-understood transcriptional activator (reviewed in Lawson et al., 2004). The crystal structures of the free protein and its co-complex with DNA are known, thus defining its interaction with the DNA operators. CAP operators are found in two distinct locations relative to the

Fig. 4 Transcription activation by cAMP/CAP. (A) Activation at Class I CAP-dependent promoters. Ternary complex of CAP and RNA polymerase (RNAP) at a Class I CAP-dependent promoter having the DNA site for CAP centered at position -61.5 relative to the transcription start site. Transcription activation involves interaction between activating region 1 (AR1) on the downstream subunit of CAP (dark green) and one C-terminal domain of an α protomer (α -CTD) (violet) indicated by a red star. The AR1- α -CTD interaction facilitates the binding of α -CTD to the DNA segment downstream of region 4 of σ (orange). The second α -CTD protomer can also contact CAP via AR1 and interact nonspecifically with upstream DNA. (B) Activation at Class II CAP-dependent promoters with the CAP site at -41.5 . Transcription activation involves three sets of CAP-RNAP interactions: interaction between AR1 of the upstream subunit of CAP (light green) and one α -CTD (violet), an interaction that facilitates binding of α -CTD to the DNA segment immediately upstream of CAP (red star); interaction between AR2 of the downstream subunit of CAP (dark green) and α -NTD (purple) (yellow star); and interaction between AR3 of the downstream subunit of CAP (dark green) and region 4 of σ (purple star). The second α -CTD protomer can interact nonspecifically with upstream DNA.

promoter. At so-called Class I CAP-dependent sites, the center of the CAP operator is positioned at about -61.5 or -72.5 upstream of the $+1$ transcription start site (Fig. 4A). At this position, the surface-exposed group of seven amino acids, called activating region I (AR1), on the downstream subunit of CAP makes a precise contact with a region in the C-terminal domain of the alpha subunit (α -CTD) of RNA polymerase (RNAP). α -CTD is attached to the N-terminal domain of the alpha subunit (α -NTD) by a long and flexible linker, allowing α -CTD to adopt various positions at the promoter. At Class I promoters it is probably tucked in between CAP and RNAP and in contact with the DNA and also in contact with the sigma subunit of RNA polymerase. It is presumed that the role of CAP (and transcription factors in general) is to provide an additional point of anchorage to increase the affinity of RNAP for the promoter; this is the classic recruitment model of transcription activation as originally proposed by Ptashne and Gann (1997).

At Class II CAP-dependent promoters, the CAP operator is centered at about -41.5 bp from the transcription start site and is nestled adjacent to the RNAP (Fig. 4B). At this position, at least three types of contact between RNAP and CAP have been detected. AR1 is still active but this time it is the upstream subunit of CAP, which is in contact with α -CTD, now located on the DNA on the distal side of CAP. Two other activating regions on CAP have been demonstrated. AR2 on the downstream subunit interacts with amino acids from α -NTD, whereas AR3 contacts region 4 of σ^{70} . Contacts between CAP and RNAP at these two positions are thought to activate transcription by a postrecruitment mechanism, facilitating isomerization of the closed complex to yield the open RNAP-DNA complex (Lee et al., 2012).

The *crp* regulon is one of the most extensive and best characterized. More than 50 targets were identified by classical studies of individually regulated genes. Transcriptome studies of both glucose-grown bacteria and *crp* mutants expanded this list to at least 200 genes (Gosset et al., 2004). Glucose affected even more genes, both positively and negatively, and this is partly due to indirect effects. Precise identification of sites on the *E. coli* chromosome that bind CAP has been achieved by chromatin immunoprecipitation and microarrays (ChIP on chip analysis) (Grainger et al., 2005). This identified 68 targets of which only 29 corresponded to previously identified sites. An alternative technique using transcripts synthesized in vitro yielded nearly 200 targets of which about 40 were previously known (Zheng et al., 2004), whereas a genomic Selex approach predicted many more (Shimada et al., 2011a). These experiments have thus confirmed the vast extent of the *crp* regulon and provided valuable information for the study of the previously unidentified target genes.

Other Global Regulators of Carbon Use

As explained earlier, a specific regulator controls the genes for use of a particular sugar. Two of the repressors of PTS operons in *E. coli* have acquired a more global function. It is perhaps significant that they are the repressors for two of the most abundant sugars:

glucose (Mlc) and fructose (FruR, renamed Cra). The role of FruR in directing the flow of carbon in either the glycolytic or the gluconeogenic direction has been described previously (see “Glycolysis and Gluconeogenesis” section).

Mlc: The glucose PTS repressor

Mlc has been shown to repress several genes related to glucose use in *E. coli*. This includes *ptsG*, encoding the major glucose transporter, *ptsHI*, encoding the central components of the PTS, and *manXYZ*, encoding a second transporter capable of transporting glucose and other hexoses. All genes so far identified as being repressed by Mlc are also controlled by CAP, so that growth on glucose has two opposing effects: it relieves repression by Mlc but at the same time lowers cAMP/CAP concentrations, provoking catabolite repression. In the case of *ptsG* and *ptsHI*, expression is greater during growth on glucose than on glycerol, but at other genes, like *manXYZ*, it is catabolite repression that dominates. It should be noted that even expression of *ptsG* requires a functional cAMP/CAP complex. There is no expression of *ptsG* in a *cya* mutant (i.e., in the complete absence of functional cAMP/CAP) but the *ptsG* promoter can work with the reduced level of cAMP/CAP present in the cell during growth on glucose.

The PTS is remarkable for the large number of regulatory functions exerted by its constituent proteins involving protein–protein interactions (Galinier and Deutscher, 2017), and PtsG is another example. Induction of Mlc-repressed genes is not due to a small molecule signal, as in the case of most prokaryotic transcription factors, but results from Mlc sequestration to membrane-bound PtsG. Mlc only interacts with dephosphorylated PtsG, which is the predominant form when PtsG is actively transporting glucose (Plumbridge, 2002). Sites on both Mlc and EIIB^{Glc} that prevent this interaction have been identified by mutagenesis (Seitz et al., 2003; Pennetier et al., 2008), and a cocrystal structure of Mlc and EIIB^{Glc} is available (Nam et al., 2008). The membrane location is an essential part of the inactivation of Mlc; the soluble EIIB^{Glc} domain is not sufficient even though it binds Mlc. The exact role of the membrane is still unknown. It has been suggested that contact with the membrane reduces Mlc flexibility so that it can no longer bind DNA (Nam et al., 2008).

The SgrS/SgrT novel sRNA/small protein pair

The *ptsG* gene is also subject to posttranscriptional regulation. The *ptsG* mRNA is rapidly degraded during conditions of phospho-sugar stress (e.g., in a *pgi* mutant growing on glucose) (Morita et al., 2003). The sugar stress initiates the synthesis of a transcriptional activator (SgrR) that promotes the synthesis of an sRNA, SgrS (sugar-related sRNA). SgrS, in the presence of Hfq, binds to the *ptsG* mRNA and prevents its translation, which in turn initiates *ptsG* mRNA degradation by RNase E (Bobrovskyy et al., 2015). The logic of this posttranscriptional regulation is to turn down expression of PtsG and to prevent the accumulation of toxic sugar phosphates. In fact, the SgrS RNA promotes a second and even more rapid response because, unlike most other sRNAs, it is a dual function sRNA that also encodes a small polypeptide, SgrT, which inhibits PtsG transport activity (Kosfeld and Jahreis, 2012; Lloyd et al., 2017). Other targets for SgrS have been identified, including repression of an alternative glucose transporter encoded by the mannose PTS (*manXYZ*) and activation of a sugar phosphatase (*yigL*) facilitating the removal of the stressful sugar phosphates (Bobrovskyy et al., 2015; Pappenfort and Vanderpool, 2015).

The carbon storage regulator, CsrA

Another regulatory system employing sRNA and affecting carbon use is the RNA-binding protein, CsrA, and its two sRNA “decoy” regulators, CsrB and CsrC. CsrA represses translation of the *glgC* mRNA for glycogen biosynthesis and represses or activates several key enzymes of central carbon metabolism. It thus participates in the switch from glycolysis to gluconeogenesis in stationary phase. The impact of CsrA during growth on glucose has been investigated using a multilevel approach (flux analysis, metabolomics, transcription, and enzyme assays), which has demonstrated that the main CsrA function is regulation of the upper glycolysis pathway and pinpointed *pfk*, encoding phosphofructokinase, as its major target (Morin et al., 2016). CsrB and CsrC are noncoding RNA carrying many copies of the CsrA RNA-binding site, which titrate CsrA. An increase in CsrB and CsrC in stationary phase results in the sequestration of CsrA by the sRNA and expression of CsrA-repressed genes. Expression of *csrB* and *csrC* is activated by the BarA/UvrY two-component system and repressed by cAMP/CAP (Pannuri et al., 2016). The levels of CsrB and CsrC are controlled by the CsrD protein, which targets the sRNAs to RNase E for degradation. CsrD has been identified as yet another target of EIIB^{Glc}. CsrD is activated by interaction with dephosphorylated EIIB^{Glc}, which decreases CsrB and CsrC levels in response to glucose transport; this interaction fine tunes CsrA regulation to PTS activity (Leng et al., 2016; Perez-Morales and Bustamante, 2016). CsrA homologues exist in numerous bacteria and have been implicated in motility, virulence, biofilm formation, and quorum sensing (Romeo et al., 2013).

The nitrogen PTS

In addition to the sugar-transporting PTS, there is a series of paralogous PTS proteins, equivalents of EI, HPr, and EIIB that are not involved in sugar uptake, in *E. coli* and a variety of other Gram-negative bacteria (Peterkofsky et al., 2006). The three proteins coded by *ptsP* (EI^{Ntr}), *ptsO* (NPr), and *ptsN* (EIIB^{Ntr}) lack any equivalent of the sugar-specific EI transporters and are proposed to have purely regulatory functions. Because *ptsO* and *ptsN* are usually localized with the *rpoN* gene, encoding σ^{54} , the nitrogen-specific sigma factor, they were termed the nitrogen or Ntr PTS and it was postulated that they have a role in coordinating the use of different carbon and nitrogen sources. The EI^{Ntr} protein has an additional N-terminal GAF domain that is not present in the sugar PTS homologue. GAF domains are found in a range of regulatory proteins and are implicated in signal perception for a variety of small molecules (including cyclic dinucleotides and 2-ketoglutarate). The presence of this conserved domain in the EI^{Ntr} proteins is

consistent with the proposed pleiotropic regulatory functions attributed to the Ntr PTS ranging from growth defects on certain carbon sources to leucine sensitivity and regulation of intracellular K^+ levels (Pflüger-Grau and Görke, 2010).

It is now well documented that EIIA^{Ntr} controls K^+ uptake by two mechanisms. First, dephosphorylated EIIA^{Ntr} interacts with and inhibits the activity of the low-affinity Trk K^+ transporter (Lee et al., 2007) and at the same time activates the expression of the high affinity KdpFABC transporter by stimulating the sensor kinase KdpD of the KdpDE two-component system in response to K^+ availability (Lüttmann et al., 2009). As K^+ levels affect the selectivity of RNA polymerase loaded with different sigma factors, K^+ homeostasis effects could explain many of the observed phenotypes of *ptsN* mutants (Lee et al., 2007; Huergo and Dixon, 2015). Two-component systems seem to be a preferred target of EIIA^{Ntr}-mediated regulation. In addition to KdpDE, EIIA^{Ntr} was also found to interact with the two-component systems PhoR/PhoB, which regulates phosphate metabolism (Lüttmann et al., 2012) and SsrA/SsrB of *Salmonella enteric* serovar Typhimurium, which controls expression of numerous genes located within pathogenicity island 2 of this bacterium (Choi et al., 2010).

The level of phosphorylation of EIIA^{Ntr} depends on the glutamine/2-ketoglutarate ratio: high 2-ketoglutarate to glutamine is the hallmark of N-starvation and stimulates EI^{Ntr} autophosphorylation (Lee et al., 2013). On the contrary 2-ketoglutarate was found to inhibit EI of the classic PTS (Doucette et al., 2011). Cross phosphorylation between the carbon PTS and the Ntr PTS was also observed. So by all these criteria, Ntr PTS is part of the machinery linking carbon utilization to nitrogen regulation (Pflüger-Grau and de Lorenzo, 2014).

Further evidence of the involvement of the Ntr PTS in carbon–nitrogen metabolism comes from the fact that the *yhbJ* gene often co-localizes and is cotranscribed with the *ptsO*, *ptsN* genes. Bacteria with mutations in *yhbJ* accumulate the enzyme Glucosamine-6P (GlcN6P) synthase (GlmS). GlcN6P is the first intermediate in the production of the essential aminosugar-containing components of the cell wall, peptidoglycan, and lipopolysaccharides. The YhbJ protein is necessary for the feedback regulation of *glmS* (Kalamorz et al., 2007) via the two small RNA (GlmZ and GlmY), which act hierarchically to activate *glmS* translation. GlmZ activates *glmS* translation but is normally prevented by the YhbJ protein, renamed RapZ for RNase adaptor protein for sRNA GlmZ. RapZ targets GlmZ to RNase E and prevents its stabilizing *glmS* mRNA. Low GlcN6P levels somehow increase GlmY sRNA levels, which act as a “decoy,” binding preferentially to RapZ and allowing GlmZ to increase *glmS* translation (Gopel et al., 2014; Bobrovskyy et al., 2015). To add yet another complexity to GlmS regulation, phosphorylated EIIA^{Ntr} has been shown to interact with GlmS and inhibit its activity, presumably in response to low glutamine levels to limit its diversion to glucosamine production (Yoo et al., 2016).

Many other proteobacteria possess homologues of the Ntr PTS proteins (EI^{Ntr}, HPr, and EIIA), often without possessing a complete carbon PTS. The Ntr PTS has been well examined in *P. putida* (see “Pseudomonades” section). *P. putida* has a total of only five PTS proteins, a specialized fructose PTS *fruBA* (where *fruA* encodes EI:HPr:EIIA^{Fru} and *fruB* EIIBC^{Fru}), plus the three proteins of the Ntr PTS, *ptsO*, *ptsN*, and *ptsP* (Velazquez et al., 2007). Both *ptsN* and *ptsO* mutations affect glucose repression of the Pu promoter of the σ^{54} -dependent xylene utilization operon. A proteome study showed that *ptsN* affected the expression of a large number of genes not just those that are glucose-repressed or σ^{54} -dependent, implying it has wide regulatory functions (Pflüger-Grau and de Lorenzo, 2014).

Catabolite Repression in Firmicutes: *B. subtilis*

In low GC-content Gram-positive bacteria, as in Gram-negative bacteria, there are several distinct pathways contributing to the preferential use of glucose over other carbon sources. The key molecule in this case is the HPr protein, the small (9 kDa) protein of the central PTS. HPr from Gram-positives, in addition to being phosphorylated by EI of the PTS on His15, can be phosphorylated at a second regulatory site, Ser46, by a specific serine kinase. The same enzyme is also responsible for the dephosphorylation of P-Ser46-HPr and so is called HPr kinase/phosphorylase (HprK/P gene *hprK*) (Mijakovic et al., 2002). HPr can be phosphorylated on His15 and Ser46 at the same time, and so four forms of HPr exist in the cell: HPr, P-His15-HPr, P-Ser46-HPr, and the doubly phosphorylated form (Fig. 5). The kinase activity is stimulated by Fru1,6P, whereas the phosphorylase activity is stimulated by inorganic phosphate (P_i). The dephosphorylation activity is not hydrolytic, but phosphorolytic, using P_i and producing pyrophosphate. A gene for a pyrophosphatase is encoded in the *hprK* operon. The presence of P-Ser46 on HPr reduces the rate of the PTS phosphorylation on His15 and the P-His15 inhibits the kinase phosphorylation on Ser46. Although the Ser46 residue exists in Gram-negative HPr, the surrounding amino acids are not conserved in enteric bacteria, which lack HprK/P, and the HprK/P of firmicutes do not phosphorylate *E. coli* HPr (Deutscher et al., 2014a).

P-Ser46-HPr and Inducer Exclusion

The relative population of the four forms of HPr depends on the growth conditions. The kinase activity of HprK/P is high during growth on rapidly metabolized carbon sources, when Fru1,6P concentrations are high. P-Ser46-HPr and the doubly phosphorylated form predominate during rapid growth on glucose with only a small percentage in the single P-His15 form, capable of transferring phosphates to the incoming sugar. Considering the strong inhibitory effect of Ser46-P on PTS-mediated phosphorylation, it would appear that the 5%–10% of HPr, which is not phosphorylated on Ser46, must be responsible for and sufficient for the rapid growth on glucose. Indeed, strains with mutations preventing Ser46 phosphorylation grow more slowly on glucose, which could be due to too much glucose uptake. Moreover, in these strains, inducer exclusion was

Fig. 5 Carbon catabolite repression in Firmicutes: *Bacillus subtilis*. Transport of glucose by the PTS and EIIICBA^{Glc} (PtsG) produces internal Glc6P, which is converted by glycolysis to Fru1,6P. Fru1,6P activates the kinase activity of HprK/P producing P-Ser46-HPr and P-Ser46,P-His15-HPr. P-Ser46-HPr interacts with the transcription factor CcpA and increases its DNA-binding affinity. The P-Ser46-HPr:CcpA complex binds to *cre* sites and inhibits transcription. P-His15-HPr levels are low and the phosphate from His15-HPr is preferentially directed to EIIA^{Glc}. Other PTS transporters such as EIIICBA^{Mtl} (MtlA) are inactive due to a lack of phosphates from HPr and the sugar-specific PTS components. In the absence of glucose transport when concentrations of Fru1,6P are low, HprK/P dephosphorylates Ser46 of HPr and the P-Ser46-HPr:CcpA complex detaches from *cre* sites. Operons encoding proteins for use of other carbon sources are transcribed in the presence of the appropriate specific signal (not shown). P in red denotes the high-energy PTS phosphates attached to histidine or cysteine residues. P in blue are the result of HPr kinase acting on HPr Ser46.

eliminated and simultaneous uptake of glucose and another sugar (mannitol) was observed. On the other hand, mutations that specifically eliminate the phosphorylase activity of HprK/P grow very slowly on glucose and all PTS sugars, because all the HPr is now in the P-Ser46 form and is unable to supply phosphates to PTS sugars. Thus, inducer exclusion of other PTS sugars by glucose is thought to be because of competition for P-His15-HPr (Deutscher et al., 2006). Inducer exclusion of non-PTS sugars is also observed in firmicutes (e.g., maltose in *L. casei* and *L. lactis*; ribose in *L. lactis*) and requires P-Ser46-HPr. P-Ser46-HPr inhibits the maltodextrin-stimulated ATPase activity of MalE1, one subunit of the ABC transporter for maltose (MalE1F1G1K1) (Monedero et al., 2008; Homburg et al., 2017). The phenomenon of inducer expulsion has also been described in *B. subtilis* and in some other bacteria. After precharging bacteria with a (nonmetabolizable) sugar, the addition of glucose causes the first sugar to be dephosphorylated and secreted into the medium. The molecular mechanism for this phenomenon is not known; experimental evidence suggests it does not require P-Ser46-HPr.

Catabolite Repression and Regulation by CcpA and the *cre* Element

AC and CAP are absent from most Gram-positive bacteria and inhibition of expression of non-PTS sugars by glucose is due to P-Ser46-HPr regulation of the CcpA repressor. In addition, a few genes are better expressed in glucose in a process called carbon catabolite activation (CCA), for example, acetate kinase (*ackA*) and phosphotransacetylase (*pta*), which allow the bacteria to get rid of excess metabolites produced by glycolysis. The CcpA protein is a LacI-type repressor, which binds to *cis*-acting sites called *cre* (catabolite response element) in the vicinity of the transcription start sites of catabolite-regulated genes. Mutations in either the *cre* site or in *ccpA* in many cases reduced or eliminated catabolite repression or catabolite activation (Fig. 5). The locations of the *cre* sites vary greatly in different operons from upstream of the promoter (for those subject to activation), to covering the promoter or transcription start site, to near the translational start site, or even within the translated region. *Cre* sites near the transcription-initiation site inhibit RNAP binding. The mechanism of CcpA inhibition by binding at the sites within the transcribed region has not been investigated but is presumably due to a “road block” mechanism inhibiting the elongating RNAP (Deutscher et al., 2006).

As in the case of CAP, several hundred genes have been identified as true or potential CcpA targets by genomic screens for *cre* sites and transcriptome and proteome analyses of wild-type and mutant strains grown with and without glucose as well as by conventional studies on individual genes. P-Ser46-HPr is an essential cofactor in the repression of most CcpA-regulated genes. The transcriptomes for the *ccpA* mutant and a strain carrying the HPr Ser46Ala mutant, (which cannot be phosphorylated by HprK/P) are very similar (Lorca et al., 2005). The two strains have similar phenotypes because the CcpA protein alone has only low affinity for its DNA targets and requires P-Ser46-HPr as a corepressor, although a few (e.g., *amyE* in *B. subtilis*) can be repressed by CcpA alone (Fig. 5). The P-Ser46-HPr concentration is highest during growth on glucose, which is the condition for maximum repression. Interestingly, these studies also revealed that CcpA controls several nitrogen-related genes (e.g., *sigL* encoding σ^{54}).

The structure of the P-Ser46-HPr:CcpA:*cre* DNA co-crystal shows that P-Ser46-HPr binds to the N-terminal subdomain of the dimerization and effector-binding domain of CcpA. The phosphate is locked into a small pocket on CcpA, and a comparison with

the structure of free (apo) CcpA reveals how the interaction with Ser46-P provokes both local and global structural changes in the subdomains. The so-called hinge helices are formed, they contact the center of the quasipalindromic *cre* site and kink the DNA and widen the minor groove, analogous to their function in LacI and PurR-operator structures. This facilitates contact between the *cre* and the helix-turn-helix motif. On the other hand, His15 of HPr is in contact with Arg296 of CcpA so that P-His15 is not compatible with HPr binding to CcpA, thus explaining the discrimination against formation of P-His15-HPr:CcpA (Schumacher et al., 2004). Glc6P and Fru1,6P are reported to stimulate catabolite repression at some loci, and they bind in the groove between the two subdomains of the effector/dimerization domain, thus bolstering subdomain movements produced by P-Ser46-HPr binding (Schumacher et al., 2007).

A protein called Crh (catabolite repression HPr) with 45% identity to HPr, is found in Bacilli and close relatives. It is also phosphorylated by HprK/P and can regulate CcpA binding. His15 is absent in Crh, which has no function in PTS sugar transport. *Crh* mutations have no effect in a strain with a wild-type HPr, but Crh can partially replace HPr function at some operators in strains carrying the HPr Ser46Ala mutation. A much lower cellular level of Crh compared to HPr might account for its limited effect in vivo. Unphosphorylated Crh, but not HPr, inhibits the activity of methylglyoxal synthase, the enzyme that initiates the methylglyoxal bypass of glycolysis under carbon overflow conditions (Landmann et al., 2011).

PTS Regulation of PRD-Containing Proteins

Although *B. subtilis* does regulate some catabolic genes and operons for use in different carbon sources by classical repressor–operator interactions, which are sensitive to a small metabolite cofactor (e.g., XylR, which controls the use of xylose, or RbsR, which controls the use of ribose), a large number of transcription regulators carry a sequence element called PRD, which stands for PTS regulation domain, which is subject to both EIIB- and HPr-dependent phosphorylations. These phosphorylations antagonistically affect, positively or negatively, the activity of the regulator. Two major types of proteins carry this domain, which exist in pairs on each protein. One class is transcriptional activators, like the LevR and MtlR proteins, and the other is transcriptional antiterminators (Stülke et al., 1998; Deutscher et al., 2014a).

Transcriptional antitermination of PTS operons

Transcriptional antitermination is a common mechanism of regulating gene expression in *B. subtilis*. A relatively long leader region is transcribed upstream of the structural gene. This mRNA can fold into alternative structures, including one resembling a classical Rho-independent transcription terminator (GC-rich stem loop followed by a series of U) and another structure destroying the terminator, the antiterminator. Various RNA-binding effectors bind to the antiterminator and stabilize it and promote read-through of the terminator and hence expression of the downstream genes. The known types of effectors include uncharged tRNA, in the case of aminoacyl-tRNA synthetase operons, or SAM, in the case of methionine/cysteine biosynthetic genes (in this case SAM binding enhances termination).

In the case of the PTS antiterminators, the structured leader RNA region is called a RAT (ribonucleotide antitermination targets). In *B. subtilis*, they are found upstream of PTS operons for transport and use of glucose (*ptsGHI*), sucrose (*sacPA* and *sacX*), aryl β -glucosides (*bglPA*), as well as *bglS* (an endoglucanase) and *sacB* (a levansucrase). A specific antitermination protein controls each operon: LicT controls *bglPH* and *bglS*, SacY controls *sacB* and *sacX*, SacT controls *sacPA*, and GlcT controls the *ptsGHI* operon. The β -glucosidase operon in *E. coli* (*bglFB*) is also regulated by a similar mechanism using the antiterminator BglG, and was one of the first studied in detail. The RAT-binding antitermination protein is usually encoded by the first gene of the operon, separated from the genes for the metabolic functions by a terminator. The RAT-binding antitermination proteins carry an RNA-binding domain (called CAT for *coantiterminator*) at their N-terminal, and two PRD domains. Each PRD domain carries two phosphorylatable histidine residues; PRD1 is preferentially phosphorylated by the sugar-specific EIIB and PRD2 by EI and HPr. The relative importance of phosphorylations at the two sites of the two PRDs varies with the different antiterminators, but the basic principle is the same. Each antitermination protein is able to undergo two types of antagonistic phosphorylations, one of which enhances the antitermination activity and the other suppresses it (Fig. 6A) (Deutscher et al., 2014a; Galinier and Deutscher, 2017).

In the absence of its particular carbon source, the EIIB domain should be predominately phosphorylated. P-EIIB is able to transfer its phosphate to the PRD1 domain of the corresponding RAT-binding antitermination protein. With PRD1 phosphorylated, the antitermination protein is inactive and cannot bind to the RAT. The loss of this phosphate, retransferred back to the EIIB domain when the corresponding transporter is actively transporting its sugar, activates the antitermination function and allows it to bind to the RAT, preventing formation of the terminator so that the downstream genes are expressed. For several operons, mutations that knock out EIIB are sufficient to produce constitutive expression of the operon, in the absence of the inducing sugar.

Some antitermination proteins are active in the absence of all phosphorylations, for example, SacY and GlcT. Thus, in *ptsH* or *ptsI* mutants, where all PTS phosphorylation is abolished, *sacB* and *ptsG* are constitutively expressed. Other antiterminators require phosphorylation by HPr on the PRD2 domain. This is the case for SacT and LicT and also for BglG from *E. coli*. Phosphorylation of PRD2 is responsible for the residual CCR of some antiterminator-regulated PTS operons in a *ccpA* strain. The level of P-His15-HPr during uptake of a rapidly metabolizable carbon source is low, since most HPr is phosphorylated on Ser46 and is unavailable for sugar phosphorylation (see “P-Ser46-HPr and Inducer Exclusion” section). All the P-His-HPr is thus engaged in phosphorylating EIIB and the incoming preferred sugar and PRD2 remains unphosphorylated and in its inactive form.

In both PRDs, there are two conserved histidines and both can be phosphorylated; one seems to be the major target for initial phosphorylation in each PRD but the second site plays a greater or lesser role as shown by mutagenesis studies. Both intradomain

Fig. 6 PRD-containing proteins. (A) Antitermination by PRD-containing antiterminators. In the absence of its specific sugar substrate, EIIB is predominately in its phosphorylated form. It can transfer a phosphate to the PRD1 domain of the antiterminator, which prevents it from binding to the RAT operator within the leader of the mRNA. The terminator stem-loop structure can form so that transcription termination occurs. In the presence of the specific sugar substrate, PRD1 is nonphosphorylated but PRD2 can be phosphorylated by P-His15-HPr, which activates the RNA-binding function of the antiterminator. The N-terminal CAT domain of the activated antiterminator binds the RAT sequence and prevents formation of the terminator, so that transcription can occur. (B) Domain organization of PRD-containing transcriptional activators. In LevR the N-terminal DNA-binding domain is followed by an NtrC-like domain and the two PRD domains are interspersed by EIIB and EIIA domains. In LicR, the domain order is different. The domains subject to negatively controlling phosphorylation by EIIB and positively controlling phosphorylation by HPr are indicated by + and – signs above the P.

and interdomain as well as interprotein phosphate transfers are possible and complicate the analysis of the role of individual His residues in each antitermination protein (Deutscher et al., 2006). Crystal structures of native LicT and a constitutively active form (where the phosphorylatable histidines are replaced by aspartates that mimic the phosphorylated state) indicate that phosphorylation produces a massive structural rearrangement of PRD2 relative to PRD1. The aspartate residues are buried in the middle of the dimer and the movement of PRD1 changes the interface between PRD1 and the RNA-binding CAT domain, presumably producing the RNA-binding conformation (van Tilbeurgh and Declerck, 2001).

PTS regulation of PRD-containing transcriptional activators

PRD-containing activators are generally large multidomain proteins with an N-terminal DNA-binding domain and two PRD domains interspersed with EIIA and EIIB domains (Fig. 6B). There are two classes known. The best characterized of the “NtrC” class is LevR, which regulates the *levDEFGsac* operon encoding a fructose/mannose PTS and an extracellular levanase. The *lev* operon is expressed from a σ^{54} promoter, which correlates with the presence of an NtrC-like domain within LevR. LevR binds to an upstream activating site (UAS) and activates expression of the *lev* operon in response to fructose. As in the case of the PRD antitermination proteins, it is subject to antagonistic phosphorylations. Phosphorylation of PRD2 by the EIIB component of the LevPTS (LevE) inhibits its activity, while phosphorylation by HPr has a positive effect, but unexpectedly occurs on the EIIA domain rather than PRD1. The second class of activators, for example, LicR or MtlR, have an N-terminal DeoR-type DNA-binding transcription activation domain followed by two PRD domains and then EIIB and EIIA domains. Once again, multiple phosphorylations by HPr and EIIB are responsible for positive and negative regulation of the activators depending on the presence of the transported sugar (Deutscher et al., 2014a; Galinier and Deutscher, 2017). Unlike other PRD-containing transcription activators, *B. subtilis* MtlR, which controls the expression of the *mtlAFD* operon for transport and catabolism of mannitol, is inactivated by phosphorylation by P-EIIA^{Mtl} rather than P-EIIB^{Mtl}. In addition, MtlR needs to interact with the EIIB domain of the mannitol-specific PTS permease MtlA. Similar to *E. coli* Mlc, MtlR is therefore sequestered to the cytosolic membrane. However, while membrane sequestration of Mlc leads to its inactivation, MtlR is activated by interaction with the membrane (Bouraoui et al., 2013).

PTS regulation of glycerol kinase

The use of glycerol is also regulated by PTS-mediated phosphorylation in *B. subtilis*. The phosphorylation target is not a transcription factor but an enzyme, the glycerol kinase, encoded by *glpK*. PEP-dependent phosphorylation of GlpK by HPr on a histidine residue

increases the kinase activity about 10-fold, thus enhancing the use of glycerol and the formation of glycerol-3P. The presence of glucose promotes the dephosphorylation of GlpK (via a reversal of the reaction with HPr) and exerts a form of catabolite repression by reducing the activity of GlpK and hence the concentration of Gly3P. Gly3P is the inducing signal for the GlpP antiterminator protein that controls the *glpFK* operon, encoding the glycerol facilitator transport protein and the kinase, so that the end result is that in the presence of glucose the *glpFK* operon is not induced. However, in the absence of glucose or another preferred PTS carbon source and the presence of glycerol, GlpK is phosphorylated by P-His15-HPr enhancing its activity and thus increasing Gly3P concentrations, so that the *glpFK* operon is derepressed (Darbon et al., 2002).

Consequences of Carbon Metabolism on Virulence

Certain bacteria have developed the capacity to survive and proliferate within animals or plants either as disease-causing pathogens or as symbionts or probiotics. To gain this capacity, pathogens have acquired specific genes, which are frequently organized in so-called pathogenicity islands and which are absent from closely related nonpathogenic species. The foodborne pathogen *Listeria monocytogenes* and the closely related nonpathogenic *Listeria innocua* are well-studied examples of a pathogen/nonpathogen pair. Only *L. monocytogenes* possesses a set of virulence genes (allowing the bacteria to cross the intestinal barrier, invade host cells, and escape phagosomes, etc.) controlled by the virulence gene activator PrfA, a CAP-like protein (de las Heras et al., 2011). *L. monocytogenes* and *L. innocua* are soil bacteria able to use a wide variety of carbon sources. Nevertheless, *L. monocytogenes* contains several carbohydrate transport systems absent from *L. innocua*. Some of them were found to be important for the switch from the saprophytic lifestyle to virulence and therefore for intracellular proliferation, such as the H⁺/hexose phosphate symporter UhpT or the presumed 2-keto-3-deoxygluconate-specific PTS permease, Lmo1971 (Deutscher et al., 2014b). These observations led to the idea that pathogens developed the capacity to survive within animals and plants in order to gain access to a broader range of carbon sources (Rohmer et al., 2011) and that detecting specific carbon sources in certain host tissues can enhance virulence.

Given the importance of carbon source availability for bacterial growth, it is not surprising that mutations affecting carbon metabolism have an impact on the virulence of numerous pathogens. In the majority of cases, these are general effects mainly related to slower growth and/or reduced fitness. In some pathogens, however, carbon sources can exert specific effects on the virulence of the bacterium. In *Streptococcus pyogenes*, the presence of glucose was found to stimulate the expression of virulence genes controlled by the transcription regulator Mga. The glucose effect seems to be mediated via two mechanisms. First, CcpA, the general catabolite repressor in firmicutes, which is activated during growth on glucose (see “Catabolite Repression and Regulation by CcpA and the *cre* Element” section), binds to *mga* promoter and enhances the expression of the gene encoding the virulence gene regulator (Almengor et al., 2007). Second, Mga has been shown to become phosphorylated by PEP and the PTS components EI and HPr. Phosphorylation of Mga probably occurs when glucose and other efficiently utilized PTS substrates are absent, a condition during which PTS proteins are mostly phosphorylated. Phosphorylation of Mga was reported to strongly inhibit in vitro expression of the Mga-regulated virulence gene *emm* (Hondorp et al., 2013).

In contrast to the virulence-stimulating effect of glucose in *S. pyogenes*, the presence of glucose was found to inhibit the virulence of *Clostridium difficile*. This pathogen is a major cause of nosocomial diseases associated with antibiotic therapy. The presence of glucose lowers the production of toxin A and B of *C. difficile* and therefore its virulence. In this pathogen, the glucose effect is also mediated via CcpA, which was found to bind upstream from the toxin-encoding genes *tcdA* and *tcdB*, although not to targets resembling known *cre* sites. In addition, formation of P-Ser45-HPr is apparently not required for the binding of CcpA to these targets, because an *hprK* mutant still exhibited glucose repression of the toxin genes. Binding of fructose-1,6-bisphosphate, the intracellular concentration of which increases during growth on glucose, seems to be sufficient for CcpA activation (Antunes et al., 2011).

Repression of virulence gene expression by various PTS-transported carbon sources, such as glucose, cellobiose, mannose and fructose, was also observed for *L. monocytogenes* (Milenbachs et al., 1997). The presence of these carbohydrates inhibits the activity of the virulence gene activator PrfA, however, in *L. monocytogenes* the repressive effect of carbohydrates on virulence genes is CcpA-independent, even though CcpA plays its usual role in repression of catabolic genes. Instead, PTS proteins, such as the EIIAB component of the glucose/mannose-specific PTS and P-Ser46-HPr, were suspected to play a role in *L. monocytogenes* virulence gene repression. Specific mutations in *prfA* were identified, which render PrfA highly active and no longer repressible by carbohydrates (Herro et al., 2005; Mertins et al., 2007). It is tempting to assume that these mutations, which were called *prfA*^{*}, might cause structural changes similar to those caused by effector binding. An interesting aspect of PrfA regulation is the observation that glucose concentrations as low as 2.5 mM strongly inhibit PrfA activity in strains grown in a minimal medium. In human blood, glucose is present at concentrations between 5 and 7 mM. Nevertheless, when *L. monocytogenes* was grown in blood, its virulence genes were strongly expressed (Toledo-Arana et al., 2009). It is not yet understood how PrfA escapes the repressive effect of glucose in blood.

Carbon Regulation and Catabolite Repression in Other Bacteria

Original mechanisms regulating carbon use and catabolite repression have been uncovered in certain bacteria, and a few examples are discussed here to demonstrate the versatility of regulatory mechanisms in bacteria.

Pseudomonades

Pseudomonades are free-living Gram-negative bacteria of which the best studied are *P. putida* and *P. aeruginosa*. They thrive in a variety of habitats, both terrestrial and aquatic. *P. aeruginosa* is an opportunist pathogen that infects the lungs and is a major agent of nosocomial infections. *Pseudomonades* are metabolically versatile and can degrade a wide range of organic and aromatic compounds especially derived from degrading plant material. Complex aromatic compounds are degraded to simple intermediates that feed into one of four chromosomally encoded central aromatic pathways (homogentisate, catechol, protocatechuate, and phenylacetate), which are responsible for cleaving of the aromatic rings (Jimenez et al., 2002). There is only one PTS sugar, fructose, but there is a complete Ntr PTS (see “The nitrogen PTS” section). Mutations in *ptsN* have several effects suggesting a role in maintaining carbon/nitrogen balance and also CCR of xylene utilization (Pflüger-Grau and de Lorenzo, 2014). Glucose is taken up via an ABC transporter, converted to gluconate-6P, and degraded predominately via the ED pathway (Nikel et al., 2015). Glucose represses the use of some hydrocarbon-degrading pathways, but succinate, some organic acids, or complex media like LB exert the strongest repression. A close CAP homologue, Vfr, exists, but cAMP levels are constant and although a *vfr* mutation affected the level of about 60 genes, and is a global regulator with pleiotropic effects, including the use of some amino acids and organic acids as carbon or nitrogen sources, CCR by succinate was not affected (Rojo, 2010).

Crc (catabolite repression control) protein was identified as a major regulator of carbon metabolism (Rojo, 2010). It has been implicated in the repression of many catabolic genes, but the pattern of repression is complex, depending on the promoter studied, the carbon source, and especially whether studies are in minimal or rich media. A metabolic-footprint analysis implied that Crc is involved in, but is not solely responsible for, the hierarchical use of carbon sources present in LB (La Rosa et al., 2016). Crc inhibits the translation of transcription factors like AlkS and BenR, which are the direct activators of the alkane and benzoate degradation pathways. Crc control of these catabolic operons is thus indirect, by keeping the levels of the direct activators low. Moreover, by preventing the expression of the first genes in a degradation pathway, Crc prevents the synthesis of the intermediates that act as inducers for subsequent steps in the pathway, and so the whole pathway is repressed (Rojo, 2010).

The Crc protein controls gene expression posttranscriptionally and was thought to function as an RNA-binding translational repressor; an adenine-rich consensus sequence (CA) was identified upstream of target genes. However experiments have confirmed that Crc does not bind RNA alone and the RNA-binding function is supplied by Hfq, the ubiquitous RNA chaperone (Milojevic et al., 2013; Moreno et al., 2015). Mutations in *hfq*, as in *crc*, relieve CCR but as Hfq binds a wide range of sRNA and mRNA, it has more dramatic consequences on cell growth. Hfq is in excess compared to Crc, and how Crc targets specific sites is still being investigated.

The level of the Crc protein varies only slightly between repressing and nonrepressing conditions. Its activity is controlled by “decoy” sRNA, CrcZ (in *P. aeruginosa*) and CrcY and CrcZ (in *P. putida*), which have multiple adenine-rich Crc consensus-binding sites and are proposed to antagonize Crc binding to its mRNAs targets by acting as decoys (Moreno et al., 2007, 2012; Sonnleitner et al., 2009). How Hfq fits into this scenario is only now being addressed. Expression of CrcZ is controlled by a two-component system, CbrA/CbrB, and RpoN. The Crc/CrcZ protein/sRNA pair resembles the well studied CsrA/CsrB, CsrC system of *E. coli* controlled by the BarA/UvrY two component system (Romeo et al., 2013). The Csr system is required for efficient switching between glycolytic and gluconeogenic carbon sources and experiments also assign a role to Crc in integrating gluconeogenic and glycolytic metabolism in *Pseudomonades* (La Rosa et al., 2015).

Specific mechanisms exist that control the expression of the novel *Pseudomonas* genes for the degradation of alkanes, phenol, and toluene/xylene. These are mostly plasmid-encoded, for example, the TOL plasmid carries genes for the conversion of toluene/xylene to benzoate/methylbenzoate, the “upper” operon, which is controlled by XylR. XylR is an NtrC-like activator that binds to a UAS and activates a σ^{54} -controlled promoter. A second “meta” operon encodes genes, which convert the benzoates to pyruvate and acetate. It is controlled by XylS, which is an AraC-like activator. These genes are subject to multilevel catabolite regulation by many other carbon sources including succinate and glucose via the ED intermediates gluconate-6P and 2-keto 3-deoxy gluconate-6P. Other specific and global factors implicated in their control include the Ntr PTS, two two-component systems, NtrCB and CbrAB, ppGpp, and others (Rojo, 2010). *Pseudomonas* have great potential in biodegradation of toxic chemicals but their utility requires precise management of their overall metabolism (Nikel et al., 2014).

Streptomyces coelicolor

Streptomycetes are aerobic, spore-forming, soil bacteria of the species actinomycetes (high-GC Gram-positives) that are important sources of secondary metabolites including antibiotics. They can use a wide range of carbon sources including insoluble materials found in soil, such as lignocellulose and chitin, and they produce a range of biotechnologically useful enzymes, like α -amylases, xylanases, and chitinases. *S. coelicolor*, the best studied, has a PTS system that is apparently dedicated to the use of *N*-acetylglucosamine (GlcNAc). GlcNAc is generated by the action of secreted chitinases on the chitin derived from fungal walls and insect cuticles in the soil. The genes for the cytoplasmic components of the PTS, *ptsH*, *ptsI*, and *crr*, as well as the GlcNAc-specific EIICB^{Nag}, are induced by GlcNAc and are controlled by a FadR family transcription factor called DasR, which also controls chitobiose uptake. DasR was originally characterized as affecting the formation of the aerial mycelium and spores. High GlcNAc concentrations prevent *S. coelicolor* from entering the developmental pathway leading to sporulating hyphae (Rigali et al., 2008).

Readily assimilable carbon sources are used preferentially and in a hierarchical fashion. Homologues of the *crp* and *cya* genes exist, but mutants are affected in germination and not catabolite repression. CCR is absolutely dependent on the glycolytic enzyme glucose kinase, GlkA, so that *glkA* mutants are no longer glucose repressible. The glucokinase activity per se is not sufficient for CCR since heterologous glucokinases can restore growth on glucose without restoring CCR, and *glkA* mutants are defective in CCR by carbon sources like galactose or glycerol, which are not metabolized via glucose kinase. The protein is constitutively synthesized, but its activity is sugar-source dependent, being high during growth on glucose and low in mannitol-grown bacteria. A complex between glucose permease (GlcP) and Glk has been suggested (van Wezel et al., 2007). Despite much effort, the exact mechanism of CCR by Glk is still elusive. One hypothesis is that it acts on the specific transcription factors of the regulated operons (Romero-Rodriguez et al., 2017). Glucose kinase has been implicated in CCR in several related bacteria, for example, *Mycobacterium smegmatis*, and in the less-related *Staphylococcus xylosum*, which also has a CcpA-mediated system.

Corynebacterium glutamicum

Corynebacteria are aerobic, rod-shaped, nonsporulating, high-GC Gram-positive soil bacteria. *C. glutamicum* has worldwide importance for the biotechnological production of amino acids, initially for glutamate and lysine (both derived from TCA cycle intermediates), but it is now also used as a biocatalyst for a range of commodity chemicals (Vertes et al., 2012). As a consequence, the central metabolism of *C. glutamicum* has been well investigated. Novel regulatory mechanisms controlling TCA cycle gene expression have been described. For example, AcnR is a TetR-family-specific repressor of aconitase. Iron homeostasis is achieved by the combined action of two repressors DtxR and RipA, which control the amount of succinate dehydrogenase and aconitase, which are both Fe-S proteins, in response to available iron. In *E. coli*, a similar iron control is achieved via Fur and the sRNA RyhB (see “The TCA Cycle and Glyoxylate Shunt” section). An opposing activator and repressor pair, RamA and RamB (regulator of acetate metabolism), controls genes for the use of acetate as a carbon source (*ack*, *pta*, *aceB*, *aceA*). In addition, the GlxR protein, a CAP homologue, represses the genes of the glyoxylate shunt, *aceBA*. Both bioinformatics and binding studies have confirmed that GlxR is a global regulator in *C. glutamicum* but, unlike CAP, GlxR is predominately a repressor (Bott, 2007; Schröder and Tauch, 2010). GlxR is sensitive to cAMP, which is reported to be high during exponential growth on glucose but low during growth on acetate, unlike *E. coli*. The level of cAMP is controlled by the action of a phosphodiesterase, encoded by *cpdA*, the deletion of which produced severe growth defects on all carbon sources tested (Schulte et al., 2017).

C. glutamicum also has an original posttranscriptional regulatory mechanism controlling the TCA enzyme, 2-ketoglutarate (2-oxoglutarate) dehydrogenase (ODHC). The small protein, OdhI, inhibits ODHC. OdhI undergoes phosphorylation by a threonine kinase, PknG, and a second kinase, in response to glutamine availability. The relative levels of phospho-OdhI and PknG determine the flux through ODHC and hence the yield of glutamate from the action of glutamate dehydrogenase on 2-ketoglutarate.

The metabolism of *C. glutamicum* is unusual in that co-utilization of several carbon sources occurs, for example, glucose with acetate, lactate, pyruvate, or fructose. On the other hand, the use of ethanol as a carbon source is repressed by glucose, even though the *adhA* gene is controlled by the RamA and RamB regulators that are responsible for control of the genes for acetate use. Co-utilization of glucose and gluconate has been shown to be a result of two functionally redundant GntR-specific repressors of the gluconate operon, acting as activators of the *ptsG* enzyme encoding the glucose transporter. The presence of gluconate causes a simultaneous decrease in PtsG levels and glucose transport and an increase in gluconate uptake. There are three PTS transporters: for glucose (*ptsG*), sucrose (*ptsS*), and fructose (*ptsF*). The genes for the central components *ptsHI* are in an operon with *ptsF* and SugR, a DeoR-type repressor, represses the expression of all five genes during growth on gluconeogenic carbon sources. SugR also represses several glycolytic genes and is reportedly sensitive to several hexose-phosphate inducing-signals. SugR along with RamA, RamB, and GlxR constitute the top of the hierarchy of transcriptional regulators in *C. glutamicum* (Schröder and Tauch, 2010; Teramoto et al., 2011).

Lactic Acid Bacteria and Bifidobacteria

Lactic acid bacteria (LAB) comprise a group of low-GC, acid-tolerant, Gram-positive bacteria, which have been exploited for centuries for the preservation of food and drinks, because the lactic acid they produce lowers the pH sufficiently to prevent the action of other spoilage agents. They carry out either homolactic (e.g., *Lactococcus* and some *Lactobacilli*) or heterolactic (e.g., *Leuconostoc*) fermentations. Considering the size reduction that has occurred in LAB genomes, typical of bacteria inhabiting nutrient-rich environments, genes for sugar utilization, including PTS transport, are predominant in the genomes (Kowalczyk and Bardowski, 2007; Monedero et al., 2007). Lactose is transported by a PTS and is metabolized via glycolysis to lactate during homofermentation. In heterofermentation, some glucose is metabolized via the pentose phosphate pathway (Fig. 1) producing CO₂, acetic acid, and/or ethanol in addition to lactic acid. Glucose transported by the PTS is the preferred sugar and produces CCR via CcpA and HPr as described for *B. subtilis* (see “Catabolite Repression and Regulation by CcpA and the *cre* Element” section). The lowering of the pH through the generation of lactic acid affects carbon metabolism and increases glucose consumption mostly through changes in enzyme activities in *L. lactis*. Analysis of the PTS and other transporters has been performed in commercially important *Lactobacillales*, for example, *Oenococcus oeni* (which is primarily responsible for malolactic fermentation in wine), and has shown significant variations between strains (Jamal et al., 2013). Specific pathways for the utilization of human milk-associated glycans have been identified (Bidart et al., 2014). Current research applies the -omics techniques and systems biology to explore and exploit the metabolic potential of these important industrial workhorse bacteria (Kok et al., 2017). *Lactobacillus* are also considered important probiotic organisms.

Bifidobacteria are anaerobic commensals of the intestinal tract and are among the first bacteria to colonize the infant gastrointestinal tract. They are particularly adapted to metabolize the complex oligosaccharides of milk (Garrido et al., 2013), but they are also able to degrade a wide range of other carbon sources including many mono- and disaccharides (e.g., lactose) and complex carbohydrates derived from indigestible plant oligosaccharides of our diet, like pectin and including the prebiotic xylo-, galacto- and fructo-oligosaccharides, which makes them the most important probiotic organism (Turroni et al., 2010; Hidalgo-Cantabrana et al., 2017). They are heterofermentative, nonsporulating Gram-positive rods, now classed as Actinomycetes (rather than lactic acid bacteria). They lack the reductive half of the TCA (Krebs) cycle. Hexoses are degraded via an unusual version of the pentose phosphate pathway (or bifido shunt) in which an original enzyme, fructose-6P phosphoketolase (*xfp*), converts Fru6P to erythrose-4P and acetyl-phosphate. The latter is converted to acetate with the production of a mole of ATP. The erythrose-4P reacts with another molecule of Fru6P to start the pathway of sequential transketolase, transaldolase reactions of the pentose phosphate pathway (Pokusaeva et al., 2011).

There are a large number of ABC-type transporters for a variety of sugars and oligosaccharides. The genes for a PTS transporter for glucose (*ptsG*) as well as *ptsH* and *ptsI* are found in *B. longum* but are only weakly expressed. A gene for a glucose permease (*glcP*) appears to encode the major glucose uptake system. *ptsG* and *glcP* are transcribed divergently and are separated by a putative RAT-controlled antiterminator. Lactose is used preferentially over glucose and represses expression of *glcP* (Parche et al., 2006). An unusual fructose-specific PTS, which forms fructose-6-P and not fructose-1-P, is present in *Bifidobacterium breve* (Maze et al., 2007). Although a lot of LacI-type transcriptional regulators have been identified on the chromosome, suggesting substrate specific regulation of the various transporters and glycohydrolases, few experimental data are available (Pokusaeva et al., 2011). Genome sequencing of individual subspecies, together with metagenomic analysis, confirm the wide range of carbohydrate metabolizing capabilities of these social gut inhabitants (Milani et al., 2015).

Conclusions

Control of carbon use involves numerous regulatory circuits operating at various levels. The enormous range of carbon sources available to bacteria must be specifically converted into simple sugar phosphates, which can then enter one of the ubiquitous pathways of central carbon metabolism. These central pathways consist of about 100 key enzymes that catalyze the formation of the energy and reducing power, as well as the precursors and cofactors necessary for bacterial growth. Major advances in our understanding of bacterial metabolism have come from the application of the large-scale genomics, transcriptome, and metabolomics techniques (Buescher et al., 2012; Nicolas et al., 2012). Together, metabolomics and flux analyses have revolutionized the analysis of metabolism in a cellular setting and identified certain original pathways and regulatory strategies. A high correlation between metabolic flux analysis data and mRNA levels from transcriptome studies suggests that carbon flux is primarily controlled at the transcriptional level. However, superimposed on this base is metabolic control, due to the large number of allosteric or otherwise regulated enzymes. Rapid kinetic experiments have demonstrated that transcriptional regulation is not sufficient to explain the rapid changes in flux observed when the carbon source is changed (Chubukov et al., 2013; Kochanowski et al., 2015; Link et al., 2015). Moreover, metabolic pathways are robust. A block in one pathway causes a local rerouting of the flux.

Under the banner of posttranscriptional regulators of carbon metabolism, we have to include several sRNAs, which have specific roles in controlling carbon utilization, for example, Spot42, SgrS (Bobrovskyy et al., 2015). In addition, there are now several “decoy” sRNAs, such as CsrB, CsrC in *E. coli*, or CrcZ, CrcY in *P. putida*, which act by titrating away RNA-binding protein regulators from their targets (Gopel and Görke, 2014).

A few key metabolites have been identified as important signaling molecules in different bacteria. For example, the glycolytic intermediate Fru1,6P is used to signal high glycolytic flux rates in numerous situations and has been proposed as the intracellular flux sensor (Kochanowski et al., 2013b). It is a key molecule to signal CCR in low-GC Gram-positive bacteria since it activates the kinase function of HprK/P and is a corepressor of the complex between CcpA and P-Ser46-HPr to repress catabolite-regulated operons. It is implicated in the switch from use of the PTS and glycolytic sugars to gluconeogenesis, since it is an effector for CggR in *B. subtilis*, FruR (Cra) in *E. coli*, and SugR in *C. glutamicum*. It is also an allosteric effector for several enzymes, including pyruvate kinase, PEP carboxylase, and glycerol kinase from *E. coli*. Another common metabolite that has emerged as a global regulator is 2-ketoglutarate (2KG). It is both a member of the TCA cycle and the substrate for glutamine biosynthesis, straddling the C–N metabolic pathways. The ratio of glutamine to 2KG is the classic signal of the nitrogen balance of the bacteria. Independently, 2KG has been shown to coordinate carbon and nitrogen utilization in other ways; it inhibits EI of sugar PTS, affects the autophosphorylation of EI^{Ntr}, and inhibits AC (Huergo and Dixon, 2015).

Synthesis of secondary metabolites is an important biotechnological application of microbes, and a lot of genetic engineering is devoted to improving yields. The cheapest carbon sources for industrial scale cultures are often a mixture of lignocellulose-derived sugars, mostly glucose and xylose. However the preferential use of glucose from the mix generates CCR with two bad consequences: acetate production and its associated acidification of the medium, which inhibits growth and, when coupled with inducer exclusion, means that the other sugar components of the feeder sugar mix are not used and are thus wasted. A lot of effort has been invested in trying to reduce the production of acetate, and some simple solutions can help considerably (e.g., the elimination of the glucose PTS in *E. coli* so that uptake is via less efficient routes generating less CCR). Intensive genetic engineering of carbon use is a major area of research in the field of microbial cell factories. For example, bacteria are being tailored to enhance production of many commercially important compounds. (Papagianni, 2012; Nikel et al., 2014; Gu et al., 2017). The advent of new-generation sequencing

techniques and large-scale metagenomic projects of bacteria from diverse ecosystems, ranging from terrestrial to aquatic and including animal symbionts has massively increased the database of bacterial genomes. Data mining these sequences shows genes and enzymes for potential polysaccharide utilization systems for a multitude of presumed, predicted, or unknown carbon compounds (Grondin et al., 2017). These genome sequences represent a rich resource for future biotechnology applications.

The emerging picture of the importance of the gut microbiota for health is fueling the analysis of metabolic pathways within different classes of the gut's inhabitants. There are clear indications of variations of the microbiome with diet, thus with available carbon sources. The variation in composition of the microbiome associated with various pathologies, especially diabetes and inflammatory bowel disease, is well documented but it is not clear whether the change in bacterial populations (dysbiosis) is a cause or an effect of the pathology (Koropatkin et al., 2012). One little observation that might relativize all the studies on *E. coli* is that the Enterobacteriaceae are only minor constituents of mammalian guts, which are dominated by Bacteroidetes and Firmicutes.

Note Added in Proof April 2019

This review was completed in the summer of 2017. Since then work on the control of carbon assimilation has continued its inexorable shift from test tube to high-through-put analyses generating data sets requiring rigorous analysis to extract the salient take-home messages. A few recent highlights are described here.

Rapidly improving analytical techniques, coupled with new approaches to mathematical modelling and data analysis have re-visited concepts that were already well established.

As an example of confirming what we thought we knew already; RNAseq and chromatin immunoprecipitation (ChIP) of cultures grown on different sugar and organic acid carbon sources identified an enlarged Cra regulon. Systems analysis of the data within the framework of a genome scale metabolic model of *E. coli* confirmed Cra and CAP are responsible for the majority of transcriptional regulation occurring in central carbon metabolism but in addition it placed Cra in the forefront of carbon metabolism in the case of non-hexose carbon sources (Kim et al., 2018). The importance of CRP and Cra was underscored when the transcriptional activity of central carbon metabolism genes was measured via transcriptional fusions with GFP (green fluorescent protein). 70% of variance over 26 environmental conditions could be assigned to "global" growth-rate- dependent regulation. The remaining "specific" transcriptional regulation was mostly correlated with the regulatory metabolites cAMP, fructose-1,6P₂ and fructose-1P—precisely the signalling molecules for CAP and Cra (Kochanowski et al., 2017). We can also mention here a new facet of CRP regulation; a lysine residue, part of AR2 (Fig. 4), can be acetylated in vivo and this modification has the potential to affect transcriptional activation by CAP (Davis et al., 2018).

Advances in metabolomics, and in particular the speed and resolution of mass spectrometric identification of compounds coupled with fast kinetic studies in cells have allowed rapid progress on the dynamics of sugar metabolism e.g. the switch from glycolytic to gluconeogenic carbon sources. The switch depends upon both transcriptional regulation and allosteric regulation and interestingly *E. coli* and *B. subtilis* adopt different strategies (Buffing et al., 2018). An alternative coarse-grained modelling approach to analyse growth transitions based on principles of flux balance was able to adequately reproduce many experimental data e.g. for diauxie (Erickson et al., 2017). Interestingly this paper and several others are coming to the conclusion that the proteome (which in large part is constituted by ribosomes and the translational apparatus) is in excess of that required for balanced growth but that this apparent wastefulness of resources maximizes the cell's flexibility to adapt rapidly to changing environmental situations e.g. between feast and famine or oxidative stress (Mori et al., 2017; Christodoulou et al., 2018). In the later case allosteric regulation was deduced to keep the excess enzymatic capacity quiescent. There is increasing interest in metabolic heterogeneity within clonal populations of cells (Takhaviev and Heinemann, 2018). A comprehensive understanding of these processes in bacteria will require application of single-cell-based techniques and especially MS-based metabolomics which, at the moment, are more easily applicable to larger yeast and other eukaryotic cells than bacteria (Duncan et al., 2019).

Another emerging area of study are "interactomes"; after protein-DNA and protein-protein interactions, interest has turned to protein-metabolite interactions (Diether and Sauer, 2017). By data-mining all available databases, Reznik et al., (2017) extracted all the known small molecules interacting with all listed *E. coli* proteins and their binding constants, and incorporated them into a mathematical model of *E. coli* metabolism. Together with published experimental data on metabolite concentrations they able to deduce how small molecules can perform both as substrates and regulatory molecules (Reznik et al., 2017).

Concerning the post-transcriptional CCR in *Pseudomonas*; more details are emerging of the how Crc/Hfq regulate translation (Sonnleitner et al., 2018). A cryoEM structure has shown a complex of two molecules of Crc sandwiched between two Hfq hexamers bound to RNA targets (Pei et al., 2019). Hfq also provides a regulatory link between iron and carbon metabolism under low CCR conditions, where Crc is mostly inactive, since it is sequestered by the sRNA, CrcY and CrcZ (Sanchez-Hevia et al., 2018). The CrcC/CrcY,Z system is also important in other members of the Pseudomonadaceae family. For example it is responsible for the preferential use of acetate over glucose in *Azotobacter vinelandii* (Martinez-Valenzuela et al., 2018). In general there are more and more examples of sRNA affecting use of sugars and CCR post-transcriptionally (Durica-Mitic et al., 2018).

Finally there are still new mechanisms of CCR to be discovered. In *Campylobacter jejuni*, which cannot grow on sugars but metabolises amino acids and organic acids via the TCA cycle, serine is the preferred carbon source. First experiments, exploring how serine reduces use of other carbon sources, hint at a role of succinate in monitoring the intracellular carbon status (van der Stel et al., 2018). How this is achieved remains to be explored.

Regulation of Replication Origin Firing

Replication Origin Firing: Assembly of Biological Switches at the Right Place and the Right Time During the Cell Cycle

There are few events during the life of a cell that are more important than initiating new rounds of chromosome replication. This is the step at which cells make the commitment to reproduce, sanctioning the time-consuming process of genome duplication as well as the subsequent events required to successfully divide. Proper regulation of the initiation step is essential to eliminate the threat of genome instability due to over or under-replication of chromosomal DNA. For this reason, sophisticated and sometimes redundant mechanisms exist to ensure that new DNA synthesis is not only tightly coupled to the cell cycle, but cannot be re-activated until the next scheduled round of chromosome duplication.

Mechanistically, the initiation step (origin firing) is best described as the assembly and activation of biological switches that ensure the proper positioning of the DNA copying machinery on the genome. Each switch is assembled and disassembled in an orderly fashion using a variety of specialized initiator proteins and a region of chromosomal DNA, termed a replication origin. New genomic DNA synthesis ensues bi-directionally from each fired origin, and the number of replication origins vary according to genome size, reviewed in Leonard and Méchali (2013). In bacteria, the small circular double-stranded genomes, averaging about 5 million base pairs (bp), carry a singular origin termed *oriC*, and once initiated, bidirectional DNA synthesis can usually be completed within about 40 min, although some bacteria require more time. Budding yeast genomes (12 million bp) are replicated within a similar time frame, but the number of replication origins increases to about 700 (and all available origins do not fire every cell cycle). Complete duplication of a metazoan genome (average size of 3 billion bp), can be accomplished in 6–8 h, but DNA synthesis is triggered from tens of thousands of replication origins. Of course, triggering DNA replication from high numbers of eukaryotic origins must be controlled with the same stringency as the single *oriC* found in bacteria.

Protein components of the firing mechanism interact with replication origins to assemble two essential complexes: 1) origin recognition complexes (ORC) that identify origins for use during the cell cycle, and 2) pre-replication complexes (pre-RC) that load, and, when necessary, activate replicative DNA helicases (the DNA unwinding activity required for replication fork movement) on origin DNA. Despite many structural similarities among initiator proteins and DNA helicases, the mechanics of origin recognition and helicase loading are fundamentally different in bacteria, archaea and eukaryotes.

Key differences also exist in the mechanisms that regulate origin firing and will be described below. In bacteria, these mechanisms are focused primarily on setting the available intracellular levels and accessibility of the active initiator protein (DnaA-ATP) needed for origin unwinding and helicase recruitment. Initiator protein availability and helicase recruitment are also cell cycle-regulated in archaea. In eukaryotes, critical regulation is shifted to the activation of pre-loaded helicases by cell cycle-dependent kinase activities. A comparison of origin recognition and helicase loading, as well as regulation of these stages in bacteria, archaea, and eukaryotes are described below.

Overview of Replication Origins

Replication origins are remarkably diverse and there are obvious differences in the level of nucleotide sequence specificity when comparing prokaryotes and eukaryotes. Bacterial origins encode nucleotide sequence motifs that serve as protein recognition sites and sequences that are regions for DNA bending and DNA unwinding. In most eukaryotes, there are fewer requirements for specific nucleotide sequences, and the lack of sequence specificity is an obvious advantage for organisms whose chromosomes carry thousands of replication origins.

Replication Origins of Bacteria

In most bacteria, *oriC* is distinguished from other regions of the chromosome by two prominent features: 1) multiple recognition sites for the principal initiator protein, DnaA, based on the consensus sequence motif [5'-TT(A/T)TNCACA-3'] (Speck et al., 1997), and 2) a region of high A-T richness, termed the DNA unwinding element (DUE), where single-stranded DNA becomes available for helicase loading (Kowalski and Eddy, 1989). In *E. coli*, the DUE contains three 13 mer repeats with consensus sequence 5'-GATCTnTTnTTTT-3' (Bramhill and Kornberg, 1988), although the nucleotide sequences of DUEs can be quite variable among different bacterial types, as can their relative locations within *oriC* (Zawilak-Pawlik et al., 2005; Leonard and Méchali, 2013). Based on an extensive bacterial origin database, it is clear that the numbers and spacing of DnaA recognition sites are also remarkably diverse, suggesting there are many ways to assemble DnaA and *oriC* into triggering complexes (Gao et al., 2013), see Relevant Website section and Fig. 1.

This article is a reprint of Alan C. Leonard, Julia E. Grimwade, Regulation of Replication Origin Firing, *Reference Module in Life Sciences*, Elsevier, 2017.

Fig. 1 Structure of replication origins in three domains of life. (A) Schematic maps of several bacterial replication origins. Relative locations of the binding sites for DnaA are shown. Binding sites with consensus sequence are indicated by red arrows, and sites that deviate from consensus by one or more bases are indicated by blue arrows. The direction of the arrows indicates the likely orientation of the arginine finger in the AAA+ domain. The region where the origins unwind (DUE) is shown by light blue boxes. Binding sites for DNA bending proteins are indicated by green boxes. (B) Schematic maps of two archaeal replication origins. Red arrows indicate the ORB Orc1/Cdc6 binding sites and blue arrows show the mini-ORB initiator binding sites. Blue boxes show the region of origin unwinding. (C) Schematic map of the *Saccharomyces cerevisiae* ARS replication origin. Relative locations the A and B1 sequences required for ORC binding (red boxes), as well as the B2 sequence where helicase is loaded and the origin is unwound (blue box), and the B3 sequence (green box) where the ABF1 chromatin modifier binds, are shown.

In addition to perfect consensus DnaA recognition motifs, some origins contain DnaA recognition sites with mismatches from consensus at one or more nucleotide locations (Fig. 1; Charbon and Lobner-Olesen, 2011; Taylor et al., 2011; Leonard and Méchali, 2013). These altered sites display reduced affinity for DnaA and occupation of these sites requires cooperative DnaA interactions, reviewed in Leonard and Grimwade (2015). In *E. coli*, a subset of low affinity sites show binding preference for the active initiator DnaA-ATP (over DnaA-ADP) and impart a requirement for DnaA-ATP in higher order pre-RC assemblies (Rozgaja et al., 2011) (see Fig. 2 and below).

Not all origins harbor their multiple DnaA boxes in single stretch of DNA. Bacterial origins from *Helicobacter* (Donczew et al., 2012), *Mycoplasma* (Cordova et al., 2002; Lartigue et al., 2003) and *Bacillus* (Moriya et al., 1999) have spatially separated clusters of DnaA recognition sites (Fig. 1). DnaA molecules bound at each cluster might interact if the DNA becomes bent during pre-RC assembly.

Fig. 2 Bacterial, archaeal, and eukaryotic initiator proteins. (A) Schematic of domains in initiator proteins, showing AAA+ domains (green) and motifs shared by DNA binding proteins (orange). HTH, helix-turn-helix; WHD, winged helix domain. (B) Cartoons of DNA binding modes and possible oligomeric structures are also shown for each domain of life. The position of each Orc protein is indicated in the DNA-bound ORC.

Replication Origins of Archaea

Studies of archaeal origin DNA reveal a mixture of attributes found in both bacteria and eukaryotes, reviewed in [Costa et al. \(2013\)](#), [O'Donnell et al. \(2013\)](#), [Kelman and Kelman \(2014\)](#), and [Ausiannikava and Allers \(2017\)](#). Although most small circular archaeal genomes carry one replication origin, several genera carry multiple origins, although origin number does not correlate with genome size ([Robinson and Bell, 2005](#); [Ausiannikava and Allers, 2017](#)). Archaeal origins are usually located adjacent to the gene that encodes for the initiator protein, Orc1/Cdc6 (named for homology to both eukaryotic proteins, see below). When multiple origin-initiator gene combinations are present, each origin appears to respond to its associated initiator ([Samson et al., 2013](#)). In some cases, Orc1/Cdc6 genes are not associated with an origin, see [Ausiannikava and Allers \(2017\)](#).

Many archaeal replication origins show some similarity to bacterial *oriC*, having distinctive AT-rich DUEs as well as clustered Orc1/Cdc6 recognition site motifs, termed Origin Recognition Boxes (ORBs), reviewed in [Leonard and Méchali \(2013\)](#) and [Wu et al. \(2014\)](#) (Fig. 1). Most ORBs are 22–35 bp with dyad symmetry and are usually mapped at two or more locations within an origin. ORBs often contain a conserved 13-bp core sequence called the mini-ORB [5'-(T/C)TNCANNNGAA(A/C)-3'], and in some archaeal origins, mini-ORBS exist as multiple (7–15) direct repeats ([Capaldi and Berger, 2004](#); [Matsunaga et al., 2010](#)). As is the case for bacteria, the number, orientation, and spacing of initiator recognition sites vary among archaeal genera ([Leonard and Méchali, 2013](#); Fig. 1).

Eukaryotic Replication Origins

DNA replication origins were first defined by their ability to confer autonomous replication to plasmids in *Saccharomyces cerevisiae* ([Stinchcomb et al., 1979](#); [Deshpande and Newlon, 1992](#)). These origins, termed Autonomous Replication Sequences (ARS), unlike the origins of higher eukaryotes, all contain a specific consensus sequence motif (autonomous consensus sequences) [5'-(A/T)TTTA(T/C)(A/G)TTT(A/T)-3'] ([Stinchcomb et al., 1979](#); Fig. 1). Adjacent to the ACS lies the B domain, which contains three subdomains ([Marahrens and Stillman, 1992](#); [Rao et al., 1994](#)). Closest to the ACS, B1 is important for ORC binding ([Rao et al., 1994](#); [Rowley et al., 1995](#)). B2 interacts with DNA helicase (in eukaryotes this is a hetero-hexamers of Minichromosome maintenance proteins, Mcm 2–7) ([Wilmes and Bell, 2002](#)). The more distant B3 is a recognition site for ARS Binding Factor 1 (Abf1) ([Marahrens and Stillman, 1992](#)), a transcription factor that mildly stimulates origin activity, probably by modulating chromatin structure and nucleosome assembly ([Ganapathi et al., 2011](#)).

Large numbers of mapped eukaryotic replication origin sequences are now compiled in a database ([Gao et al., 2012](#)), and it is clear that origins of yeast strains other than *S. cerevisiae* and metazoans display little sequence specificity with the exception of CpG

islands, GC-rich regions, and G-quadruplexes (Cayrou et al., 2011, 2012, 2015; Valton et al., 2014). The exact role of these features in origin activity remains unclear.

Overview of Initiator Proteins and Origin Recognition Complexes (ORC)

Protein initiators from all domains of life share similar structural and functional features, although there are obvious mechanistic differences in the way origin firing is accomplished. All initiators carry domains for DNA binding and, as members of the AAA+ (Adenosine triphosphatases Associated with various cellular Activities) family of proteins, also carry domains able to bind and hydrolyze ATP (Iyer et al., 2004; Duncker et al., 2009). AAA+ domains often play a role in initiator oligomerization and the assembly of higher order structures (short oligomers, helical arrays, and cracked rings), see review by Duderstadt and Berger (2008). The coupling of initiator activity to ATP binding and hydrolysis creates a convenient on-off switch that can be used to prevent over-replication.

Initiator proteins must interact with replication origins in reproducible ways during every cell cycle, and ORC are unquestionably important for both origin identification and correct step-wise assembly of pre-replication complexes. Despite their pivotal roles, striking differences exist among bacterial, archaeal and eukaryotic ORC. Eukaryotic initiators assemble into a highly conserved hetero-hexameric ORC prior to interacting with origin DNA using little or no nucleotide sequence specificity (Bell and Stillman, 1992; Quintana and Dutta, 1999). ORC remains bound to DNA throughout the cell cycle, but during late M/early G1 phase it recruits DNA helicase (Mcm 2–7); see reviews in DePamphilis (2005) and Li and Stillman (2012). In contrast, assembly of the bacterial equivalent of ORC is determined by high affinity initiator (DnaA) interactions with recognition site motifs encoded into the nucleotide sequence of *oriC* (Miller et al., 2009). Archaeal ORC is the most enigmatic version since origin DNA interactions with the archaeal initiator, Orc1/Cdc6, have aspects of both eukaryotes and bacteria (Wigley, 2009; Bell, 2012). Rather than forming a complex, in many archaea each Orc1/Cdc6 may act as both ORC and helicase loader combined.

The Bacterial Initiator DnaA and bORC

All bacterial origin firing depends on higher order assemblies of the DnaA protein initiator, but each *oriC* recognition site is occupied by a DnaA monomer (Speck et al., 1997; Weigel et al., 1997). DnaA's C-terminal domain (IV) with helix-turn-helix structure (Erzberger et al., 2002) is responsible for double-stranded DNA binding (Schaper and Messer, 1995), and signature amino acids of DnaA make base-specific contacts (Fujikawa et al., 2003; Fig. 2). DnaA is active in the ATP-bound state (Sekimizu et al., 1987) and the amino acids required for ATP-binding and hydrolysis are localized within an internal domain (III) (Fig. 2). Proteins that interact with DnaA usually contact the N-terminus (domain I) (Simmons et al., 2003), located on the end of a flexible stalk (domain II) whose length varies among bacterial types (Messer et al., 1999; Zawilak-Pawlik et al., 2005; Fig. 2).

Both ATP and ADP forms of DnaA are capable of self-oligomerization mediated by domain I-domain I interactions (Simmons et al., 2003; Zawilak-Pawlik et al., 2017). DnaA-ATP also self-oligomerizes when an arginine finger in one molecule's domain III contacts the ATP bound to an adjacent protomer, combined with additional domain III contacts (Erzberger et al., 2006; Fig. 2). The DNA-binding domain (domain IV) of DnaA-ATP also folds up toward domain III, helping to stabilize the intermolecular interactions, leading to the formation of a compact helical filament (Duderstadt et al., 2011). Compact DnaA-ATP filaments bind single-stranded DNA through a central channel formed by domains III and IV, and are reported to melt short DNA duplexes, presumably by stretching the helix (Duderstadt et al., 2011). However, the compact helical filament has very low affinity for double-stranded DNA (Duderstadt et al., 2011) and if a DnaA oligomer is formed on double-stranded DNA during pre-RC assembly, it must have an alternative structure that is not yet characterized.

DnaA does not readily form into complexes in the absence of DNA (Duderstadt et al., 2010), and for this reason, a true structural equivalent of eukaryotic ORC (see below) does not exist. However, it is possible to define the bacterial ORC (bORC) as the DnaA-*oriC* complex that, like the eukaryotic ORC, persists during extended periods of the cell cycle and serves as a scaffold for the recruitment of additional proteins that lead to origin DNA unwinding and helicase loading (Miller et al., 2009). Surprisingly, on native supercoiled DNA, the DUE of *oriC* spontaneously unwinds in the absence of associated protein (Kowalski and Eddy, 1989), and the bORC constrains *oriC* DNA to prevent unwinding until a complete pre-RC is assembled (Kaur et al., 2014). In *E. coli*, bORC comprises DnaA occupying the available three high affinity DnaA recognition sites (R1, R2, and R4) (Kd in the range of 4–20 nM) (Miller et al., 2009; Fig. 3). Since these recognition sites in *E. coli* are widely separated, DnaA-DnaA interactions within ORC are likely to form DNA loops. Clustered high affinity DnaA recognition sites are found within most bacterial *oriCs* (Gao et al., 2013) and these sites are also expected to be occupied in a similar fashion to *E. coli*, unless the availability of DnaA were extremely limiting. Each DnaA molecule in ORC is able to recruit additional DnaA molecules and nucleate the formation of DnaA oligomers during pre-RC assembly, see below Miller et al. (2009) and Rozgaja et al. (2011).

Eukaryotic ORC

The proteins comprising the heteromeric eukaryotic ORC (Fig. 2) are well-studied and the ORC structure was recently determined, see for example, Chen et al. (2008) and Bleichert et al. (2015). Although five members share attributes of AAA+ proteins, only Orc1 and Orc5 bind to ATP, and only ORC1 has intrinsic ATPase activity mediated by contact with an arginine finger (Klemm et al., 1997;

Fig. 3 Multistep assembly of nucleoprotein complexes at replication origins. (A) Formation of pre-RC in *E. coli*. *E. coli oriC* is maintained throughout most of the cell cycle with DnaA (either nucleotide form) bound to R1, R2 and R4, with Fis binding adjacent to R2. Dotted lines indicate possible interaction between DnaA molecules. Immediately before DNA replication initiates, the remaining, lower affinity sites are filled in a specific order, indicated by numbers; this step requires DnaA-ATP (DnaA-ATP is shown by lighter green domain III; low affinity DnaA-ATP sites shown by dark blue arrows, low affinity sites without preference shown as light blue arrows). As DnaA binds, Fis is displaced, IHF binds between R1 and R5, and the DNA strands in the DUE separate. The single-stranded DNA region is stabilized by binding of oligomeric DnaA-ATP filaments, which assist in loading the DnaB/C (helicase/helicase loader) complex. DnaC must leave the pre-RC for helicase activation. (B) Formation of pre-RC in budding yeast. ORC is bound throughout the cell cycle at the A domain and B1 domains. Orc1–5 proteins encircle the DNA, while Orc6 binds to Orc5 and Orc3. In G₁, when CDK levels are low, bound ORC recruits Cdc6, which binds in the gap between Orc1 and Orc2. After Cdc6 binds, Cdt1/Mcm2–7 proteins are recruited, and the Mcm2–7 complex (helicase) is loaded onto double-stranded DNA in the B2 domain, forming the pre-RC. Cdt1 is displaced prior to helicase activation.

Neuwald et al., 1999; Iyer et al., 2004). Orc1-5 proteins have winged helix domains that are typical for DNA binding proteins (Speck et al., 2005; Duncker et al., 2009; Fig. 2). Orc6 lacks any homology to the other ORC components, does not bind to DNA and is composed of tandem cyclin-box folds similar to transcription factor IIB (Balasov et al., 2007). Orc6 is not necessary for ORC–ARS binding, but is required for early stages of pre-RC assembly (Chen et al., 2007).

Eukaryotic ORC are dynamic complexes that are assembled in stages: Orc2/Orc3 interacts with Orc4/5, Orc1 is then added to Orc2/Orc3 to complete a ring in the order Orc1–Orc4–Orc5–Orc3–Orc2, and Orc6 then binds directly to Orc3 and Orc5 (Vashee et al., 2001; Chen et al., 2008). Orc1's ATPase requires the conserved arginine residue from Orc4 for catalytic activity, see Bleichert et al. (2015). ORC is initially inactive, but an ATPase-dependent conformational change produces a gapped ring that permits the DNA binding elements in ORC's central channel to encircle DNA (Bleichert et al., 2015). The gap (between ORC1 and ORC2) must be filled by the interaction of Cdc6 to begin pre-RC assembly (Sun et al., 2012). Orc1, Orc4, and Orc6 in higher eukaryotes also carry auxiliary domains for DNA/chromatin interactions (e.g., the BAH domain of Orc1) (Noguchi et al., 2006; Müller et al., 2010).

The Archaeal Initiator Orc1/Cdc6

Although the replication origins of archaea carry distinct initiator recognition sites, similar to bacteria, their initiator protein, Orc1/Cdc6 is clearly more similar to eukaryotic initiators, reviewed in Wigley (2009), Bell (2012), Kelman and Kelman (2014), and Ausiannikava and Allers (2017). Despite structural similarities, archaeal Orc1/Cdc6 interacts with double-stranded DNA differently than ORC, using both N-terminal AAA+ and C-terminal winged-helix domains (Dueber et al., 2007, 2011; Gaudier et al., 2007; Fig. 2). This unique bipartite interaction makes few base-specific contacts, but produces local distortions in origin DNA. Like DnaA, Orc1/Cdc6 is active in the ATP-bound form, but unlike DnaA, ATP does not appear to regulate interactions with origin DNA (see below). In some archaea, Orc1/Cdc6 binding to proximal miniORBs is cooperative (Capaldi and Berger, 2004; Grainge et al., 2006) suggesting that, oligomeric ORC or pre-RC structures may be formed that are analogous to those observed for DnaA. However, there remains no clear consensus regarding the ability of Orc1/Cdc6 to bind cooperatively or persist on origins as an ORC-like complex.

Assembly of Pre-RC for Loading/Activation of DNA Helicase

Loading DNA helicase onto the replication origins of both eukaryotes and bacteria requires building a pre-RC by adding proteins to ORC, but there are noteworthy differences in the way this is accomplished, see recent reviews by Bell and Kaguni (2013), Yao and O'Donnell (2016), and Parker et al. (2017). In bacteria, there are three steps: 1) pre-RC are assembled by progressively adding DnaA molecules to *oriC* DNA, guided by recognition sites, 2) the DUE is unwound by the assembled pre-RC, and 3) pre-RC associated DnaA, with assistance from specialized helicase loader proteins position the helicase onto the available single-strands. In eukaryotes, inactive DNA helicase (Mcm2–7) complexes are loaded (with the assistance of several loading factors) onto ORC-associated, double-stranded origin DNA in late M or G1 stages of the cell cycle (referred to as origin licensing). The Mcm complex is then activated prior to the onset of S phase by association with additional protein regulators, some of which must be phosphorylated by regulatory kinases. Origin DNA unwinding is not detected until after helicase activation. The archaeal DNA helicases resemble those in eukaryotes, and archaea also contain analogs of many of the eukaryotic helicase activating proteins. The order of DNA unwinding and helicase loading in archaea remains uncertain and is probably type-specific.

DNA Unwinding and Helicase Loading in Bacteria

Although the mechanism responsible *oriC* unwinding remains uncertain, the bacterial pre-RC is, generally speaking, a DNA stress-inducing machine that introduces bends, kinks and less well defined topological changes within *oriC*. Despite the lack of mechanistic details, it is clear that precise timing of replication onset requires orderly and reproducible addition of DnaA during pre-RC assembly. To achieve this, DnaA additions are guided by *oriC*-encoded recognition sites (Leonard and Grimwade, 2011; Rozgaja et al., 2011; Fig. 3). In *E. coli*, these are low affinity ($K_d > 200$ nM) and become occupied sequentially during pre-RC assembly (Schaper and Messer, 1995; Messer et al., 1999; Rozgaja et al., 2011).

Low affinity site arrays are found in the gap regions between two high affinity recognition sites (R1–R2 or R2–R4) (Rozgaja et al., 2011; Figs. 1 and 3). Within an individual array, all sites face in the same direction and are separated by two base pairs (Rozgaja et al., 2011; Figs. 1 and 3). Most importantly, three of the low affinity sites in each array bind DnaA-ATP preferentially, coupling pre-RC assembly to the availability of this form McGarry et al. (2004).

Filling the arrayed recognition sites requires assistance from a DnaA molecule residing at proximal high affinity site, and this nucleation step utilizes DnaA's domain I (Schaper and Messer, 1995; Miller et al., 2009). Thus, pre-RC assembly order is determined by proximity of high and low affinity recognition sites with right side sub-complexes preceding those on the left (Rozgaja et al., 2011; Fig. 3). Each bound DnaA molecule bends double-stranded DNA (Schaper and Messer, 1995), and although the DnaA oligomer assembled is not well characterized, the position of DnaA boxes is likely to increase torsional stress for DUE unwinding.

Although a likely common feature of bacterial *oriCs* (Charbon and Lobner-Olesen, 2011; Leonard and Méchali, 2013), low affinity DnaA recognition sites remain difficult to identify by nucleotide sequence alone and some bacterial origins may lack these sites. As an alternative, closely spaced high affinity recognition sites may be used for cases where DnaA synthesis rates are very low or

availability is restricted. It is also important to not rule out the role of DNA topology in the ability of DnaA to access some recognition sites in select bacterial types, and supercoiling dependent DnaA binding in *oriC* is reported in *Helicobacter pylori* (Donczew et al., 2014).

As noted above, DnaA-ATP interacts with single-stranded DNA as a compact filament, which is likely to enhance unwinding and stabilize the single-stranded DNA (Duderstadt et al., 2010). Once *oriC* is unwound, oligomers can extend from DnaA residing at a DUE-proximal recognition site (Duderstadt et al., 2010; Richardson et al., 2016). As is the case for all DnaA oligomers assembled on double-stranded *oriC* DNA, specialized arrays of nucleotide motifs, termed trio sequences (3'-GAT-5', 3'-AAT-5' and 3'-GAA-5'), specify single-stranded DNA interactions in a wide range of bacterial types (Richardson et al., 2016).

Bendable DNA regions are often located in bacterial replication origins and DNA bending is known to be regulated by accessory DNA bending proteins, such as IHF or Fis, see Swinger and Rice (2004) and Gimenes et al. (2008). By moving high and low DnaA recognition sites into or out of proximity, these proteins can dynamically promote or prevent the assembly of the pre-RC (Fig. 3). This is the case for *E. coli* where Fis-catalyzed DNA bending in the right half of *oriC* represses pre-RC assembly (Ryan et al., 2004). As the available levels of DnaA rise in the cell, Fis is displaced by DnaA, and a second bending protein, IHF, gains access to a recognition site in the left half of *oriC* (Ryan et al., 2004). The resulting bend brings a high and low affinity recognition site into proximity (R1 and R5M) as a nucleation switch for the subsequent stage of low affinity DnaA site filling (left array) and *oriC* unwinding (Rozgaja et al., 2011; Ozaki et al., 2012). Switches of this kind add precision to the triggering mechanism during the cell cycle and set the levels of DnaA necessary to fire origins within a narrow time window. DNA bending switches may also modulate *oriC* firing by utilizing bending proteins whose synthesis is coupled to growth rate or environmental cues.

The replicative helicase in *E. coli* is a homo-hexameric protein (DnaB), and is complexed with a specialized loading protein, termed DnaC, before it is recruited to the unwound origin by the pre-RC, reviewed in Bell and Kaguni (2013) (Fig. 3). DnaA then loads one DnaB-C complex on each of the separated strands. Domains I and III of DnaA are involved in the helicase loading step (Seitz et al., 2000; Abe et al., 2007). Although the exact details of this step may vary among bacterial types, the DnaC molecule of the DnaB-DnaC complex is proposed to act as a molecular adapter by interacting with DnaA-ATP at or near the end of an oligomeric filament extending into the DUE (Mott et al., 2008). Helicase loading must be performed on both the top and bottom strands of the DUE, suggesting different DnaA molecules within the oligomer are responsible, see Bleichert et al. (2017). Once loaded, helicase activation requires the dissociation of DnaC, and this step may not occur until the loaded helicase interacts with the replicative primase in the presence of ATP and other ribonucleotides (Chodavarapu et al., 2016). DnaC is not a universally-used protein and in Gram positive bacteria the helicase (termed DnaC) is loaded by two proteins (DnaD and DnaB) (Smits et al., 2011). In some bacteria, DnaA alone may be capable of loading helicase (Robinson et al., 2010).

Helicase Loading and Activation in Eukaryotes and Archaea

The intricate choreography of helicase loading and activation in eukaryotes is described in several excellent reviews (Bell and Kaguni, 2013; Tognetti et al., 2015; Parker et al., 2017), and will only be summarized here (see Fig. 3). The licensing step requires two regulatory factors, Cdc6 and Cdt1, which are sequentially recruited to the origin by ATP-bound ORC. Cdc6 is an ORC remodeling factor that stabilizes the ring-like ORC on origin DNA and generates new binding sites for the recruitment of Cdt1 (Speck et al., 2005; Sun et al., 2012). Cdt1 is the Mcm2-7 loader, acting in a similar fashion to DnaC in *E. coli*. When associated with Mcm2-7, Cdt1 is recruited to ORC through interactions with Orc6 (Chen et al., 2007). Loading of the Mcm2-7 requires ATP hydrolysis of Cdc6 which allows DNA to gain access to a central channel in the Mcm2-7 ring due to alterations in protein conformation associated with the release of Cdt1 (Samel et al., 2014). An initial Mcm2-7 complex is loaded on the winged helix domain face of ORC, followed by a second Mcm2-7 complex in a head to head configuration (Evrin et al., 2014). Bound Cdc6 inhibits helicase activity and must also be displaced by ATP hydrolysis (Chang et al., 2015).

The post-loading events required for helicase activation require a large number of protein factors. At the onset of S phase, two kinase activities: the Dbf4-dependent Cdc7 kinase (DDK) and S phase cyclin-dependent kinase (CDK) phosphorylate Mcm2-7 which allows Mcm2-7 to interact with the helicase activating factor Cdc45 (complexed with additional non-catalytic chaperone factors that differ somewhat between yeasts and metazoans) (Petojevic et al., 2015). Since helicase loading can only take place when CDK levels are low, further loading is blocked during this stage, ensuring once only triggering during the cell cycle. CDK is also required to assemble a second activating complex known as GINS (Go Ichi, Ni San) (Takayama et al., 2003). GINS is a tetramer that assembles into a higher order complex, also with a variety of non-catalytic chaperones, prior to interacting with Mcm-Cdc45 (Gambus et al., 2006). The resulting large protein complex of Cdc45-Mcm2-7-GINS, referred to as CMG (Moyer et al., 2006), is the DNA unwinding-proficient, activated version of the eukaryotic replicative helicase. It remains unclear why so many proteins are necessary to activate eukaryotic helicases, but cells may benefit by having many targets for checkpoint regulation or a variety of chaperones to accommodate many chromatin configurations.

The archaeal Mcm complex is a homo-hexamer with significant structural similarities with eukaryotic Mcm 2-7 (Chong et al., 2000), and there are also archaeal homologs of GINS and Cdc45 suggesting that archaea must share the eukaryotic activation scheme (Marinsek et al., 2006; Xu et al., 2016). Unlike eukaryotes, archaeal Cdc45 (two copies) and GINS form an extremely stable complex before binding to the N terminal domains of Mcm to produce an activated DNA helicase (Xu et al., 2016). The archaeal helicase loading step also deviates from both bacteria and eukaryotes since there are no analogs of either DnaC or Cdt1, see Tye (2000). No loader protein appears to be needed and Orc1/Cdc6 is able to perform the role of Cdt1 in helicase recruitment. ATP-bound Orc1/Cdc6 is required for proper helicase loading with Mcm interacting directly with the ATPase

domain (Samson et al., 2016). Thus, a one to one relationship exists between each Orc1/Cdc6 and Mcm for recruitment. The placement of ORB sites on either site of the DUE, is consistent with directional helicase loading on each of the available single strands of DNA (Samson et al., 2013; Fig. 1).

Regulating Origin Triggering During the Cell Cycle

Origin triggering is regulated by diverse mechanisms, some of which are specifically tuned to cells with either few or many replication origins on their genomes. In bacteria, the triggering mechanism must accommodate rapid growth rates wherein new rounds of chromosome replication must be triggered before previous rounds are completed. For this reason, regulation is based almost exclusively on controlling the availability of active initiator DnaA-ATP during each cell division cycle. In eukaryotes, the availability of ORC proteins and the helicase activation step are dependent on cell cycle-coupled kinase activities. Chromatin state also appears to play an important role in the regulation of origin firing. In archaea, regulation appears to focus primarily on the availability and ATP-bound state of Orc1/Cdc6.

Bacteria

There is little evidence for cell cycle-specific gene expression or kinase activity involvement in the triggering of most bacterial replication origins, but triggering does depend on achieving the appropriate threshold level of DnaA-ATP available to interact with *oriC*. Although DnaA-ATP levels in bacteria are due predominantly to new synthesis, the levels and availability of DnaA-ATP at *oriC* fluctuates during the cell cycle (Kurokawa et al., 1999), due to post-triggering mechanisms that are coupled to the movement of replication forks. These include: 1) DnaA-ATP inactivation by hydrolysis, 2) titration of DnaA away from *oriC* by newly replicated recognition sites located around the genome, 3) blocking DnaA access to *oriC*, and 4) reactivating inactive DnaA-ADP into active DnaA-ATP (Fig. 4), although there is considerable variety among bacterial types. In *E. coli*, conversion of DnaA-ATP to DnaA-ADP is accomplished primarily by interactions with a replication fork-associated protein, Hda, which stimulates the hydrolytic activity of bound DnaA in a process termed Regulatory inactivation of DnaA (RIDA) (Katayama and Sekimizu, 1999; Keyamura and Katayama, 2011). However, post-triggering mechanisms to stimulate DnaA-ATP hydrolysis are not effective in all bacteria (Smits et al., 2011; Bonilla and Grossman, 2012), and consistent with this idea, Hda is not a widely-conserved protein.

Fig. 4 Regulatory mechanisms ensuring that replication origins fire only once per cell cycle. (A) In *E. coli*, levels of DnaA-ATP are regulated to control origin firing. Mechanisms that increase DnaA-ATP levels are in green, and mechanisms that decrease DnaA-ATP levels are in red (see text for details). DnaA-ATP access to *oriC* is also regulated by the blocking/anti-cooperativity factor SeqA, which prevents DnaA from re-binding to low affinity sites immediately after initiation. (B) In eukaryotes, several mechanisms regulate the levels and/or activity of proteins involved in eukaryotic replication origin firing (see text for details). Mechanisms that increase activity/levels are shown in green, and mechanisms that lower activity/levels are shown in red.

DnaA may be titrated away from *oriC* by individual DnaA recognition sites dispersed over the chromosome or by localized clusters at one or more positions on the genome (Roth and Messer, 1998; Christensen et al., 1999). In *E. coli*, the *datA* locus, distanced from *oriC* by over 450,000 bp (Ogawa et al., 2002) titrates any DnaA-ATP displaced from *oriC* into a complex that hydrolyzes DnaA-ATP by an Hda-independent mechanism (Kasho et al., 2017). Similar regulation exists in *B. subtilis* where clusters of DnaA recognition sites are also found at eight intergenic regions on the Bacillus chromosome (Ishikawa et al., 2007). The protein YabA, found in several Gram-positive bacteria (Noirot-Gros et al., 2006), tethers DnaA to replication forks and reduces its availability to *oriC* (Schenk et al., 2017).

Factors exist in many bacterial types that have the ability to block DnaA accessibility or affect its cooperative binding/oligomerization during the cell cycle. In *E. coli*, low affinity recognition sites are blocked for about 1/3 of the cell cycle (Campbell and Kleckner, 1990) following each new round of DNA synthesis by the sequestration protein, SeqA (Lu et al., 1994; Slater et al., 1995), which recognizes and binds to newly-replicated hemimethylated GATC sites found in high numbers within *oriC* and in the *dnaA* promoter. High affinity recognition sites in *oriC* are not sequestered and can remain occupied throughout the cell cycle to immediately reset the bacterial ORC (Nievera et al., 2006). Origin binding of the blocking factor CtrA in *Caulobacter* is also coupled to DNA methylation state (Quon et al., 1998). Other blocking/anti-cooperativity factors, may be independent of methylation, such as AdpA in *Streptomyces* (Wolański et al., 2012), MtrA in *Mycobacteria* (Rajagopalan et al., 2010), HP1021 in *Helicobacter* (Donczew et al., 2015), as well as SirA (Rahn-Lee et al., 2011), Soj (Scholefield et al., 2011) and DnaD (Bonilla and Grossman, 2012), Spo0A (Boonstra et al., 2013), and YabA (Soufo et al., 2008; Scholefield and Murray, 2013) in *Bacillus*.

In rapidly growing *E. coli*, new rounds of DNA replication must be triggered prior to the completion of previous rounds to ensure each daughter inherits the correct genome content. Under rapid growth, there may be insufficient new DnaA-ATP synthesis to allow for proper initiation timing at all copies of *oriC*. A DnaA-ADP recharging system, dependent on two chromosomal loci termed DnaA recharging sequences (DARS) raises the levels of DnaA-ATP (Fujimitsu et al., 2009). DARS sites contain a specific arrangement of DnaA recognition sites, but the mechanism for recharging remains unclear. DnaA also interacts with the acidic phospholipids of the cytoplasmic membrane in *E. coli* (Crooke, 2001; Regev et al., 2012) and like DARS, membranes can recharge DnaA-ADP (Garner and Crooke, 1996).

Eukaryotes and Archaea

Besides the CDK and DDK-dependent regulation required for helicase activation described previously, there is clear evidence that multiple mechanisms ensure once-*per-cycle* origin triggering in eukaryotic cells, reviewed in Arias and Walter (2007), Drury and Diffley (2009), and Siddiqui et al. (2013). Although many of the regulatory details remain obscure and considerable diversity exists among eukaryotic cell types, CDK-dependent prevention of re-replication is accomplished at both the origin licensing as well as origin firing steps by component destruction, blockage of complex assembly, and removal (export) of components from the nucleus (Fig. 4).

In most eukaryotes, the Cdc6 helicase loader is limiting during the cell cycle and synthesis is tightly restricted to late G1, to ensure that no origin is retrIGGERED prematurely, see Arias and Walter (2007). To prevent relicensing, ubiquitin mediated degradation of Cdc6 is activated by S-phase CDK phosphorylation and phosphorylated Cdc6 is also transported out of the nucleus, see Drury and Diffley (2009). CDK-dependent phosphorylation of ORC (ORC2 and 6) also inhibits ORC/Cdc6/Mcm2–7 establishment to ensure once per cell cycle replication (Chen and Bell, 2011; Fernández-Cid et al., 2013; Frigola et al., 2013). CDK phosphorylates any Mcm2–7 not loaded onto origin DNA resulting in its export from the nucleus (Labib et al., 1999; Nguyen et al., 2000).

In metazoans, licensing is blocked by a CDK-independent protein factor geminin, which binds to and inhibits Cdt1 activity (Diffley, 2004; Caillat and Perrakis, 2012). Geminin is degraded during mitosis (McGarry and Kirschner, 1998; Li and Blow, 2004). Cdt1, as well as several other DNA replication/repair proteins, are also degraded by an S phase-coupled mechanism that is dependent on chromatin-bound PCNA, the processivity clamp for DNA polymerase delta (Arias and Walter, 2006; Havens and Walter, 2009; Coleman et al., 2015). Cdt1 ubiquitination precedes proteolysis and requires that a specialized motif found in Cdt1 interact directly with PCNA to recruit ubiquitin ligase (Havens and Walter, 2009).

Recent studies suggest chromatin structure plays a dynamic role in determining which origins will be triggered during any given eukaryotic cell cycle, reviewed in Cayrou et al. (2012), Méchali et al. (2013), Rhind and Gilbert (2013). Dynamic nucleosome positioning can enhance origin activity in an open chromatin state or occlude origins and block access to pre-RC factors (Kurat et al., 2017; Rodriguez et al., 2017). A permissive chromatin environment is a major characteristic of active transcription promoters and a correlation exists between transcription activity and enrichment for DNA replication origins (Cayrou et al., 2015; Sequeira-Mendes and Gutierrez, 2015; Miotto et al., 2016). However, interactions of pre-RC proteins with adjacent nucleosomes may also be important (Azmi et al., 2017). For example, ORC interactions with chromatin are regulated by the BAH domain of the ORC1 subunit in *S. cerevisiae* and in human cells (Noguchi et al., 2006; Müller et al., 2010). Histone modification also plays a role in the choice of DNA replication origins and in the regulation of their activation (Aggarwal and Calvi, 2004). At a higher level of chromosomal organization, the timing of replication domains strongly correlates with long-range chromatin interactions (Pope and Gilbert, 2013; Pope et al., 2014) and DNA replication origins may be clustered within open chromatin or chromatin loops (MacAlpine et al., 2010; Ryba et al., 2010).

Since archaea are not known to carry genes for cyclin kinases or Cdt1, cell cycle regulation must be accomplished by either changing the levels or activities of Orc1/Cdc6 and/or Mcm proteins (Akita et al., 2010; Lindås and Bernander, 2013; Samson et al., 2016), but this is not a simple issue to resolve due to the diversity of archaeal types. For example, the levels of Orc1/Cdc6 are reported to fluctuate during the cell-cycle in *Sulfolobus solfataricus* and *Sulfolobus islandicus* (Robinson et al., 2004; Samson et al.,

2016), but not in *Sulfolobus acidocaldarius*, or *Pyrococcus abyssi* where the protein is abundant and remains associated with origins (Matsunaga et al., 2007; Duggin et al., 2008).

In order to recruit DNA helicase, Orc1/Cdc6 must be bound to ATP (Samson et al., 2016). The ATPase domain of Orc1/Cdc6 interacts with the winged helix domain of the Mcm complex, and spontaneous ATP hydrolysis prohibits re-replication by blocking further helicase recruitment (Samson et al., 2016). A once-*per-cycle* switch of this type may require deactivation/reactivation factors, but these are not yet identified.

Glossary

aa Amino acid.

Aptamer Part of a riboswitch, RNA sequence that can bind a small ligand.

Antisense RNA RNA that is transcribed in opposite direction to its target RNA and interacts with its target by basepairing.

bp Base pair.

CDS Coding sequence of mRNA.

FMN Flavin mononucleotide.

FRET Fluorescence resonance energy transfer.

Hfq Host factor 1 for replication of phage Q β . Abundant heat-stable RNA chaperone found in 50% of all sequenced bacterial species.

Inc Incompatibility group. Two plasmids are incompatible, when they cannot coexist in the same cell without selective pressure, because they share the same replication control elements.

kD Kilodalton.

nt Nucleotide.

ORF Open reading frame.

Riboswitch Sensory RNA, part of the 5' untranslated leader region of an mRNA which can adopt two mutually exclusive conformations depending on the presence or absence of a small ligand molecule.

RNAP RNA polymerase.

RNA pseudoknot A single RNA molecule consisting of ≥ 2 helical segments connected by ≥ 1 single-stranded segment that often results in a complex tertiary structure.

RNase III Double-stranded RNA (dsRNA) specific endoribonuclease.

RNA thermometer Sensory RNA, part of the 5' UTR of an mRNA, which can respond to temperature changes by adopting an open or closed conformation.

Ribozyme Catalytic RNA. Currently, nine natural ribozymes are known.

SAM S-adenosyl methionine.

SD Shine-Dalgarno sequence; equivalent to the ribosome binding site.

sRNA Small RNA, term used for bacterial RNAs, which are mainly untranslated and in size range between 50 and 500 nt.

TA module Chromosomally encoded toxin-antitoxin system.

TMP Thiamine monophosphate.

TPP Thiamine pyrophosphate.

Transcription attenuation Mechanism that includes two alternatively folded structures in the 5' leader region of an mRNA, a terminator structure characterized by a rho-independent terminator, yielding a truncated RNA that terminates upstream of the SD sequence, and a read-through structure, that allows transcription of a full-length mRNA. Attenuation can be achieved by various means, for example, binding of an antisense RNA, prevention of binding of an aminoacylated tRNA, translation of a leader peptide, binding of a modified or unmodified protein etc.

Two-component system Regulatory system composed of a sensor histidine kinase and a response regulator that can be phosphorylated at asparagine residues.

UTR Untranslated region of mRNA.

Defining Statement

Small RNAs in microorganisms can be divided into cis- and trans-encoded base pairing sRNAs, sRNAs acting via protein binding, sensory RNAs, and RNAs with specific functions like tmRNA, RNase P, 4.5S RNA, and CRISPR RNAs. The article summarizes our current knowledge on the biochemical properties of these RNAs, their mechanisms of action, and their biological functions.

[☆]*Change History*: September 2016. J Kreth, S Brantl, and J Merritt updated keywords, abstract and the text of this entire article, updated further reading and added a new figure 9.

This article is an update of S. Brantl, RNAs, Small etc., *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 409–437.

Introduction

Small RNAs (sRNAs) have become increasingly recognized as critical gene expression regulators—both in prokaryotes and in eukaryotes. Already in the 1970s, about 10 small abundant RNAs were found in *Escherichia coli* using a two-dimensional gel electrophoretic approach. However, the function of most of these RNAs remained elusive long after their discovery. Since 2001, systematic computer-based searches and more recently, RNA-seq studies, have revealed that bacteria encode a surprisingly vast number of unannotated non-coding RNAs. In many cases, this can be upwards of 10–20% of the entire genome. By 2012, approximately 140 sRNAs have been identified in *E. coli* with an additional >160 putative sRNAs predicted computationally or detected via RNA-seq. Only a fraction of these have experimentally validated functions, indicating the difficulties that still exist to unravel their mechanisms of action. For species outside of the enteric bacteria, the number of characterized sRNAs drops precipitously. Thus, our current mechanistic understanding of sRNA biology is heavily biased for sRNAs produced in the enteric bacteria, principally *E. coli* and *Salmonella*. However, with the tremendous growth in the number of prokaryotic RNA-seq studies, a much more detailed picture of sRNAs is slowly emerging and new discoveries are increasingly being reported from species other than the traditional model organisms. In recent years, it has also become increasingly evident that sRNAs play a central role in virulence factor regulation for both plant and animal pathogens, which has greatly increased the general awareness and interest in sRNA biology.

Principally, small RNAs can be divided into two major groups: The first group is comprised of antisense RNAs that regulate gene expression by complementary base pairing. Among these antisense RNAs, we can distinguish between cis- and trans-encoded RNAs (Fig. 1). Cis-encoded RNAs contain regions of perfect complementarity to their target RNAs, and consequently, form perfect duplexes with them. By contrast, trans-encoded RNAs are only partially complementary to their targets and typically form imperfect partial duplexes with usually multiple target RNAs. In both cases, the interaction between antisense RNA and target mRNA results in post-transcriptional inhibition or activation of target gene expression. The second group of sRNAs comprises RNAs that regulate gene expression either by binding to proteins or serving as “sponges” to titrate regulatory RNAs from their targets. In addition to these two major groups of RNAs, other prokaryotic small RNAs with diverse functions have been discovered and investigated over the past 30 years. Among them are tmRNA acting in trans-translation for increased translational efficiency, the RNase P ribozyme required for 5' end processing of tRNA precursors, the 4.5S RNA component of the prokaryotic signal recognition particle, and CRISPR RNAs that confer adaptive immunity to phages and foreign genetic elements.

Small Regulatory RNAs

Location and Sources of Riboregulatory Elements

Initially identified on extra-chromosomal and mobile accessory genetic elements like plasmids, transposons, and bacteriophages, sRNAs are also encoded on the chromosomes of bacteria. Considering that the majority of bacteria reside in surface-attached communities (biofilms) that are notorious for their high rates of horizontal gene transfer, the actual pool of accessible sRNAs is dynamic and likely extends beyond what is chromosomally-encoded by an individual organism. Overall, most characterized sRNAs are non-coding, expressed from independent promoters, and have specific transcription terminator sequences. A recent survey comparing over 900 validated bacterial sRNAs and 23,000 intergenic regions (IGRs) indicated that sRNAs occur more frequently in IGRs. sRNA-encoding IGRs tend to be longer with a higher degree of conservation compared to the average IGRs. IGRs might also be

Fig. 1 Overview of cis- and trans-encoded antisense RNAs. Antisense RNAs are drawn in red, sense RNAs in blue. Black rectangles denote promoters.

the preferred breeding ground for the acquisition and/or evolution of new sRNAs, since mutations in IGRs tend to have less pronounced effects on overall cellular fitness. sRNAs can also be generated through RNase-dependent processing of larger transcripts, particularly at the 5' or 3' ends of transcripts. Furthermore, 5' untranslated regions (UTRs) of mRNAs can act as regulatory RNA as well, further extending the repertoire of riboregulatory elements. Dual-function sRNAs encode both a functional riboregulatory sRNA and a peptide/protein. The recent discovery of riboregulatory protein-encoding mRNAs has revealed that our functional understanding of mRNA is likely oversimplified and demonstrates yet another bacterial mechanism of riboregulatory gene expression control. Specific examples are given throughout the text.

Cis-Encoded sRNAs

The majority of cis-encoded antisense RNAs (asRNAs) were found in so-called accessory genetic elements (i.e., plasmids, phages, and transposons). Among the first of these RNAs were discovered in 1981 in the *E. coli* plasmids ColE1 and R1 where they regulate replication, and hence, control plasmid copy numbers. Subsequently, in a wide variety of plasmids, phages, and transposons, cis-encoded antisense RNAs were found and intensively characterized over the past 35 years. In plasmids, antisense RNAs regulate replication, maintenance, and segregational stability. In phages, they have a fine-tuning function in the decision between lysis and lysogeny. In transposons, they control transposition frequency. Meanwhile, an increasing number of chromosomally encoded cis-acting sRNAs have been characterized as well. Among them are a variety of type I toxin-antitoxin (TA) modules, such as the *txpA*/RatA TA module from *Bacillus subtilis* and the *symE*/SymR TA module from *E. coli*. Cis-encoded asRNAs also regulate a variety of genetic pathways, such as the *IsrR* sRNA of *Synechococcus* that regulates the production of the photosynthesis component *IsiA* or the *GadY* sRNA of *E. coli* involved in the acid stress response via regulation of *GadX* and *GadW* synthesis (Fig. 2A). Table 1 provides a sampling of the diverse cis-encoded antisense RNAs for which targets have been identified.

Mechanisms of action

Thus far, the majority of antisense RNA interactions result in post-transcriptional inhibition of target RNA function, but a variety of activating mechanisms have been found as well. Characterized regulatory mechanisms employed by cis-encoded antisense RNAs are discussed below and summarized schematically in Fig. 2A.

Transcription attenuation

This mechanism was first discovered for the replication control of the staphylococcal plasmid pT181 (in 1989) and later (in 1993) for the streptococcal plasmids pIP501 and pAM β 1, belonging to the Inc18 family. Transcription attenuation has been only detected for one antisense RNA in Gram negative bacteria, in a virulence plasmid of *Shigella flexneri*. The nascent *rep* mRNA from these plasmids can adopt two mutually exclusive conformations. Upon binding of the antisense RNA, a terminator stem-loop is induced in the nascent *rep* mRNA, and consequently, transcription is terminated prematurely upstream of the *rep* ribosome binding site (RBS) preventing Rep protein synthesis and ultimately, replication. If the nascent *rep* RNA escapes antisense RNA binding, it can refold by complementary base pairing into an alternative structure that prevents terminator formation and allows transcriptional read-through. This results in Rep protein synthesis and consequently, replication (see Fig. 2A). The antisense RNA binds and exerts its inhibitory effect only during a short window of time and without a helper protein. RNAIII of plasmid pIP501 is composed of 4 stem-loops L1 to L4, of which the first two are dispensable both in vivo and in vitro. Loops L3 and L4 must both interact simultaneously with the complementary loops L1 and L2 of RNAII (*repR* mRNA) to yield efficient inhibition. The inhibition rate constant of RNAIII has been determined to be $1 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$, whereas the pairing rate-constant was 10-fold lower, indicating that inhibition occurs faster than stable duplex formation between RNAIII and its target, RNAII. Structure probing of the complex between RNAII and RNAIII of pIP501 showed that it is not a complete duplex. The intracellular concentrations of both RNAII and RNAIII have been determined to be 1–2 μM and 50nM, respectively, ensuring a large excess of the regulator over its target. Normally, antisense RNAs that regulate plasmid copy numbers are short-lived with half-lives of 1–2 min. to quickly correct fortuitous copy number fluctuations. However, RNAIII is unusually long-lived with a half-life of ~ 30 min. Consequently, a second control element called CopR is needed for proper control. The dimeric CopR protein binds asymmetrically at its two consecutive sites in the major groove of the DNA upstream of the *repR* promoter pII and represses *repR* transcription ~ 10 -fold. CopR also prevents convergent transcription from the sense and antisense promoters, thereby indirectly increasing transcription at the antisense promoter pIII. The concerted action of both control elements is required for efficient replication control.

Both the pIP501 and the pT181 systems work similarly and have been studied biochemically in terms of secondary structures of sense and antisense RNAs, binding kinetics, and sequence requirements for efficient inhibition (see below).

Translation inhibition

The inhibition of target mRNA translation by occlusion of its RBS is a commonly employed mechanism of cis-encoded sRNAs. In the plasmid pLS1, RNAII is complementary to the *repB*-RBS and directly inhibits ribosomal loading. The same mechanism is used by the FinP antisense RNA that blocks the RBS of *traJ*, an activator of conjugal transfer operons in the F and R1 plasmids. Duplex formation between the FinP sRNA and *traJ* mRNA is catalyzed by the FinO protein, which prolongs FinP half-life by protecting it against RNase E degradation (Fig. 2A). Additionally, the Sok and RNA I sRNAs (plasmids R1, pAD1) and RNA-OUT (IS10) use translational inhibition. In the former two cases, toxin synthesis from their respective plasmid addiction modules is inhibited, whereas in the latter, transposase expression is regulated. In the replication control systems of plasmid R1 and the IncB/Inc α

For plasmid encoded RNAs, the antisense RNA of best studied example is given.

?, no mechanism proposed.

^aMechanism proposed but not experimentally substantiated.

plasmids, the sRNAs CopA and Inc inhibit translation of a leader peptide, which is required for efficient Rep translation via translational coupling. A variety of chromosomally encoded type I toxin-antitoxin (TA) systems also utilize various mechanisms of translation inhibition to modulate the production of toxins. Both type I and type III TA modules utilize cis-encoded sRNAs as antitoxins. However, only type I systems act post-transcriptionally upon toxin mRNAs, whereas type III antitoxins act post-translationally by binding directly to toxin proteins. For type I systems, toxin mRNA translation can be either directly repressed or indirectly via the modulation of toxin mRNA stability. The former mechanism is employed by the *symE*/SymR TA module of *E. coli*. SymR is a 77-nt sRNA transcribed from the opposite DNA strand as the SymE toxin. The +1 site of SymR is located within the 2nd codon of the *symE* ORF. Thus, its region of complementarity encompasses both the *symE* translation initiation codon and its RBS, resulting in potent translation inhibition when the mRNA/sRNA molecules are duplexed. A similar mechanism is observed in the *fst-Sm*/srSm TA module of *Streptococcus mutans*. However, in this case, the region of complementarity does not include the RBS of *fst-Sm* toxin mRNA, rather the hybrid duplex begins 7-nt downstream of the RBS to sequester the translation initiation codon. Thus, it is not always necessary to directly occlude the RBS to efficiently inhibit mRNA translation. A similar result has also been demonstrated for the *B. subtilis* *bsrG*/SR4 type I TA system. In this case, the bifunctional antitoxin SR4 binds to the 3' region of the toxin mRNA promoting its degradation, in addition to inhibiting toxin translation by introducing a structural change far upstream near the *bsrG* RBS.

Inhibition of primer maturation

Replication via a plasmid-encoded primer (known as RNAII) has thus far only been observed for ColE1 plasmids and its relatives. These plasmids are among the few known antisense RNA regulated plasmids, which also do not encode their own replication initiator proteins, and therefore, rely solely on host proteins. To initiate plasmid replication, a persistent RNAII/DNA hybrid must be formed at the plasmid origin and this hybrid is itself dependent upon RNAII first forming specific secondary and tertiary structures during RNAII synthesis. If RNAII is able to adopt its mature structure, it can bind at the plasmid origin, be further extended by DNA polymerase I, and then processed by RNase H to yield the final primer required for DNA replication. Conversely, to inhibit plasmid replication, duplex formation with the RNAII pre-primer and the plasmid-encoded antisense RNA called RNAI occurs to prevent RNAII primer maturation. The kissing complex between RNAI and RNAII is stabilized by the plasmid-encoded Rom protein, but can also occur spontaneously in the absence of Rom. It is worth noting that ColE1-derived cloning vectors like pUC18/19 replicate at greatly increased copy numbers (200–300 copies/cell), due to a mutation in RNAI that impairs its inhibitory function (Fig. 2A).

Inhibition of an activator RNA pseudoknot

Rep protein production in IncB, IncX, IncK, IncL/M plasmids requires a long-distance activator RNA pseudoknot. As in R1, a leader peptide ORF, *repY*, must be translated to promote the formation of an activator pseudoknot structure instead of an alternate mRNA structure that would otherwise occlude the *rep* RBS. The corresponding antisense RNAs have two functions, as they prevent leader peptide translation, and consequently, also prevent activator pseudoknot formation (Fig. 2A).

Promotion of mRNA degradation or processing

For many years, only a few antisense RNAs were known to influence mRNA stability, among them the λ -OOP RNA that facilitates RNase III-dependent decay of the *cII* mRNA as well as RNA α expressed from plasmid pJM1 that affects the stability of both *fatA* and *fatB*-mRNA in *Vibrio anguillarum*. For the IsrR sRNA involved in the iron stress response of *Synechocystis* 6803, IsrR-mediated inhibition of its target mRNA *isiA* occurs through a codegradation mechanism. Under normal growth conditions, IsrR remains highly abundant in the cell and will trigger the degradation of duplexed *isiA* mRNA. However, during iron deplete conditions, *isiA* transcription is induced, causing its accumulation in the cell. Once *isiA* abundance exceeds that of the inhibitory sRNA IsrR, *isiA* mRNA can be translated to yield the iron stress-induced protein A (IsiA). Likewise, a number of type I TA systems from *B. subtilis*

have also been shown to utilize an antisense RNA-mediated target mRNA degradation mechanism. For example, the aforementioned RatA and *txpA* TA module encodes >100 bp region of complementarity within the 3' portion of both molecules that supports duplex formation and serves as a substrate for RNase III and RNase Y cleavages. The degradation of duplexed *txpA* mRNA prevents its translation and the subsequent accumulation of toxin within the cell. A variation of this theme was observed for the *B. subtilis* *bsrG*/SR4 TA module. Here, 3' complementarity between the SR4 antitoxin and *bsrG* mRNA similarly creates a substrate for RNase III activity. However, duplex formation serves the additional function of remodeling a *bsrG* secondary structure to sequester its RBS, thus further suppressing translation of the transcript. Duplex formation with cis-encoded antisense RNAs can trigger stabilizing RNA processing events as well. The *E. coli* GadY/*gadX* system is an example. The *gadX* gene is the first gene of the *gadXW* operon and encodes a transcription regulator involved in the glutamate-dependent acid resistance system. In addition, *gadX* mRNA also possesses 3' complementarity with the GadY sRNA that is directly responsible for increasing *gadX* mRNA levels by increasing its stability due to processing via RNase III. Duplex formation between GadY and *gadX* mRNA creates a substrate for RNase III cleavage of the *gadXW* transcript resulting in two products that are more stable than the full-length transcript.

Binding kinetics, binding pathway, and requirement of RNase III

For many systems, antisense/sense RNA binding pathways have been studied in detail and binding kinetics measured. Analyses of pairing rate constants have usually yielded values of $\sim 10^6 \text{ M}^{-1} \text{ s}^{-1}$. The initial contact between antisense and sense RNA can either occur between two complementary loops (many replication control systems) (Fig. 2 B) or between a loop and a single-stranded region (e.g., RNA-IN/RNA-OUT of IS10, *hok*/Sok of plasmid R1) (Fig. 2 C). In the first example, simple helix progression in both directions is topologically impossible due to accumulating torsional stress. Therefore, loop-loop initiating systems require a subsequent interaction at a distal site to remodel its secondary structure and circumvent this limitation. Regardless of whether a one-step or multi-step pathway is utilized (see Fig. 2B and C), the final result of the interaction is a complete duplex that is often degraded by the double-strand specific RNase III, which requires a ≥ 20 bp duplex (two helical turns) as a minimal substrate (shown for CopA/CopT, RNA-OUT/RNA-IN and *hok*/Sok). However, despite the fact that cis-encoded antisense RNAs are fully complementary to their targets, the formation of complete duplexes is sometimes too slow to account for the observed biological effects. Instead, many antisense RNAs mediate inhibition by forming complexes that involve limited numbers of base pairs with their targets. As has been demonstrated for R1, ColE1, pIP501, and the IncB/IncX type plasmids, full duplex formation is not required for control. For the replication control of R1, a partially paired binding intermediate is sufficient for inhibition in vivo. Similarly, in vitro analyses of two antisense RNA-mediated transcription attenuation systems of Gram-positive bacteria, pT181 and pIP501 also yielded partial duplexes. In pIP501, complexes between the complementary loop pairs of sense and antisense RNA form and progress into the stems, but the spacer between the two stem-loops remains single-stranded and is unimportant for inhibition.

For the replication control system of plasmid R1, the binding pathway between the CopA sRNA and its complementary target within the *repA* mRNA (called CopT) has been elucidated in detail (Fig. 2B). Binding initiates with an unstable loop-loop interaction (kissing complex) that is converted into an extended kissing complex. Later, a single-stranded region is required to overcome the torsional stress created upon the unidirectional progression of this loop-loop interaction. Next, a binding intermediate is formed, which contains a four-helical junction. This intermediate is transformed into a stable inhibitory complex, which is only a partial duplex and is slowly converted into a stable duplex cleaved by RNase III. This step-wise binding pathway and four-helix junction is conserved in the IncX and related plasmids as well.

In contrast to R1 and IS10, in λ OOP RNA, RNase III cleavage was found to be necessary for control. This is probably because the mechanism exerted by λ OOP RNA is principally mRNA degradation, whereas in the other systems, translation is inhibited before degradation occurs.

Pervasive antisense transcription

Despite the limited number of chromosomally derived cis-encoded asRNAs with known regulatory functions, data from numerous transcriptomic studies have demonstrated that most bacteria produce a surprisingly large number of antisense transcripts. The abundance of asRNAs seems to vary widely among species, but thus far, it appears that Gram positive organisms produce a greater abundance compared to the enteric species. It is currently unclear whether the majority of these asRNAs have *bona fide* riboregulatory functions (like those described previously) or whether they serve some other purpose, if any at all. In a comparative study of *E. coli* and *S. enterica*, it was found that both of these closely related organisms produce similar abundances of asRNA. However, only about 14% of these asRNA transcripts appeared to be conserved between them and there was no obvious conservation of promoter elements, even among strains of the same species. This contrasted sharply with a concurrent comparison of protein-encoding genes, leading to the suggestion that most asRNAs are likely nonfunctional. Another comparative genomic analysis of a more diverse collection of species further observed that the abundance of asRNAs in a species correlates exponentially with its genomic A+T content. This result argues in favor of a transcriptional noise hypothesis that stipulates most asRNAs are transcribed due to the creation of spurious promoters having sequences similar to the sigma 70 (σ^{70}) consensus –10 (TANAAT). However, studies of double stranded RNA (dsRNA) in both *Staphylococcus aureus* and *E. coli* seem to support an opposite conclusion. In *S. aureus*, it was estimated that 75% of sense RNAs from annotated genes are subject to processing from RNase III due to their interaction with asRNAs. In *E. coli*, specific enrichment of dsRNA yielded 316 potentially functional asRNAs that are also subject to processing from RNase III. In both cases, it appears that asRNA plays a significant role in shaping global gene expression patterns, particularly via the action of RNase III. Thus, it is currently difficult to reconcile the lack of evolutionary conservation among asRNA with their observed function as global regulators of gene expression.

Trans-Encoded sRNAs

The first chromosomally derived trans-encoded RNA, MicF, was detected in 1984. This 93 nt sRNA forms a 20 bp imperfect RNA duplex with the translation initiation region of the *ompF* mRNA encoding a porin of the *E. coli* outer membrane. By the mid 1990s, only a handful of trans-encoded sRNAs were known, such as Spot 42, DsrA, and OxyS. However, it is now known that most, if not all, bacteria produce a tremendous number of trans-encoded sRNAs. Many of the *E. coli* sRNA genes are conserved in closely related pathogens, such as *Salmonella* and *Yersinia* species, indicating they are likely functional regulators. A large number of these characterized sRNAs regulate porins of the *E. coli* outer membrane. Many other sRNAs still await target identification and functional characterization. In Gram positive bacteria, a smaller, but increasing number of sRNAs has been characterized and a much larger number of putative sRNAs has been predicted computationally or detected via RNA-seq. Table 2 gives an overview of characterized trans-encoded sRNAs.

Biological functions

Trans-encoded sRNAs have been implicated in a wide variety of regulatory pathways. Often, sRNAs appear to function in the fine-tuning of gene regulation, which is reflected by a frequent lack of severe phenotypes upon their deletion or overexpression. However, trans-encoded sRNAs typically control diverse regulons and exhibit functional redundancies. In these instances, the full influence of sRNA regulation upon a particular pathway may only be obvious after mutating multiple sRNAs within the same cell. An example of such redundancy is found among the 4 Qrr sRNAs of *V. cholerae*, which together play a central role in regulating quorum sensing in this species. Some of the better-characterized sRNAs from enteric bacteria regulate pathways such as iron transport and storage (RyhB), membrane composition (MicA, MicC, MicF, RseX, OmrA/B, RybB, InvR), carbohydrate utilization (Spot 42), stress response to phosphorylated carbohydrates (SgrS), and stationary phase regulation (OxyS, DsrA, RprA). In some instances, a single sRNA regulates a set of mRNAs involved in the same metabolic pathway. One example is RyhB of *E. coli* that regulates at least 6 target mRNAs, *sodB*, *sdhD*, *acnA*, *fumA*, *bfr*, *ftn* and *shiA*, encoding proteins required for iron transport and storage. Similarly, two σ^E -controlled sRNAs of *Salmonella*, MicA and RybB, destabilize various outer membrane porin mRNAs as part of the envelope stress response. While MicA selectively facilitates the decay of *ompA* mRNA, RybB was found to accelerate the decay of at least 8 major outer membrane porin mRNAs, *ompA*, *ompF*, *ompS*, *ompC*, *ompN*, *ompW*, *ompD*, and *fadL*. In other cases, one mRNA can be the target of several sRNAs that inhibit or activate its expression under different environmental conditions. One such example is *rpoS* mRNA encoding the *E. coli* stationary phase sigma factor σ^S . At low temperatures, DsrA sRNA activates translation of *rpoS* mRNA, whereas under conditions of oxidative stress, RpoS levels are down-regulated by OxyS. A third sRNA, RprA, activates *rpoS* mRNA translation under conditions of osmotic shock and cell surface stress. A fourth *rpoS*-activating sRNA, ArcZ, is repressed by the aerobic/anaerobic-sensing ArcA-ArcB TCS under anaerobic conditions.

Mechanisms employed by trans-encoded antisense RNAs

Currently, translation inhibition is the most frequently observed regulatory mechanism employed by trans-encoded sRNAs and there are three different ways sRNAs can achieve this: (i) by the direct occlusion of an RBS, (ii) by the induction of an mRNA secondary structure that occludes the RBS, or (iii) by blocking a ribosome standby site required for efficient translation (Fig. 3). Interestingly, in some cases translational inhibition is accompanied by mRNA degradation, whereas in others, no mRNA degradation has been observed. In some instances, trans-encoded sRNAs can specifically target an mRNA for degradation, which ultimately prevents translation as well. In a minority of characterized examples, trans-encoded sRNAs are known to activate translation of their target mRNAs. In such cases, sRNA base pairing either promotes access to an RBS or ribosome standby site or it directly inhibits RNase cleavage of an mRNA. Common mechanisms employed by trans-encoded sRNAs are discussed below and summarized in Fig. 3.

Translation inhibition

Translation inhibition by direct occlusion of the RBS Direct RBS occlusion by sRNA base pairing is the most frequently observed mechanism of translation inhibition, shared by both cis- and trans-encoded antisense RNAs. Examples of trans-encoded sRNAs using this mechanism include OxyS, Spot42, MicA, MicC, MicF, RyhB, and SgrS. For this mechanism, sRNA base pairing overlaps with the target RBS and/or its adjacent 5' or 3' regions. For MicA and MicF, their complementary regions include the *ompA* and *ompF* RBSs, respectively, whereas for MicC, the two complementary regions within *ompC* are 6 and 16 bp immediately upstream of the RBS. In the case of OxyS, two interacting regions were found, 7 bp overlapping the target *fhlA* RBS and a 9 bp interaction about 25 nt downstream of the AUG start codon. For SgrS, a 23 bp discontinuous stretch of complementarity was found to overlap the RBS and start codon of *ptsG* mRNA. However, mutational analyses revealed that only 6 bp around the RBS are crucial for regulation.

Translation inhibition by induction of structural changes downstream from the RBS SR1 from *B. subtilis* is one of the few sRNAs known to employ this mechanism. SR1 interacts with *ahrC* mRNA encoding a transcriptional activator of the arginine catabolic operon. Both RNAs share seven complementary regions in the 3' regions of both SR1 and *ahrC* mRNA. The distal complementary region (called Region G) is located ~100 nt downstream from the RBS of *ahrC* mRNA. Binding of SR1 induces structural alterations in all seven complementary regions as well as immediately downstream of the *ahrC* RBS and upstream of region G. These changes in secondary structure effectively inhibit translation initiation as demonstrated by toeprinting analysis. Thus, base pairing interactions far from the RBS can still potentially prevent ribosome assembly at the RBS.

Table 2 Examples of trans-encoded antisense RNAs

<i>sRNA (length)</i>	<i>Target RNA(s)</i>	<i>Biological function</i>	<i>Mechanism of action</i>	<i>Control of expression</i>
<i>Escherichia coli</i>				
MicA (72 nt)	<i>ompA</i>	Membrane composition	Translation inhibition	σ^E , stationary phase
MicC (109 nt)	<i>ompC</i>	Membrane composition	Translation inhibition and mRNA degradation	Low temperature
MicF (93 nt)	<i>ompF</i>	Membrane composition	Translation inhibition	High temperature, salt, HU, H-NS, Lrp, OmpR, SoxS, MarA, Rob
RseX ($\approx$ 90 nt)	<i>ompA</i> , <i>ompC</i>	Membrane composition		?
OmrA/OmrB (88/82 nt)	<i>cirA</i> , <i>fecA</i> , <i>fepA</i> , <i>ompT</i>	Iron transport, protease		High osmolarity, OmpR
IpeX (167 nt, on prophage)	<i>ompC</i> , <i>ompF</i>	Membrane composition	mRNA degradation?	Phage-encoded porin gene
RybB (78 nt)	<i>ompC</i> , <i>ompW</i>	Membrane composition		σ^E
RyhB (90 nt)	<i>sodB</i> , <i>sdhD</i> , <i>acnA</i> , <i>fumA</i> , <i>bfr</i> , <i>ftn</i> , <i>shiA</i>	Iron metabolism, shikimate permease	Translation inhibition and mRNA degradation, translation activation	Fur, iron
Spot42 (109 nt)	<i>galK</i>	Galactose utilization	Translation inhibition	cAMP-CAP, glucose
SgrS (227 nt)	<i>ptsG</i>	Glucose transport	Translation inhibition (mRNA degradation)	SgrR, phosphorylated, carbohydrate stress
DsrA (87 nt)	<i>rpoS</i>	Stationary phase	Translation activation	Low temperature, osmotic shock, LeuO?
RprA (106 nt)	<i>hn-S</i>	Stationary phase	Translation inhibition	Osmotic shock, cell surface stress, RcsB
	<i>rpoS</i>	Stationary phase	Translation activation	
OxyS (109 nt)	<i>rpoS</i> , <i>fhfA</i>	Stationary phase, Formate metabolism	Sequestration of Hfq, Translation inhibition	Oxidative stress
GcvB (130 nt)	<i>oppA</i> , <i>dppA</i>	Peptide transport	Post-transcriptional control	GcvA, GcvR, glycine excess
IstR-1 (75 nt)	<i>tisB</i>	Antitoxin	Translation inhibition by competing with standby ribosomes	–
<i>Salmonella typhimurium</i>				
MicA (72 nt)	<i>ompA</i> , <i>X</i>	Membrane composition	Translation inhibition?	σ^E
RybB (78 nt)	<i>ompC</i> , <i>D</i> , <i>F</i> , <i>N</i> , <i>S</i> , <i>W</i>	Membrane composition	Translational inhibition? mRNA degradation	σ^E

Translation inhibition by regulation of a ribosome standby site or a translational enhancer A well-characterized example of this mechanism involves the regulation of *E. coli* *tisB* mRNA by the sRNA IstR1. A ribosome standby site has been found for *tisB* located approximately 100 nt upstream of the *tisB* RBS and this site is required for efficient translation of the TisB toxin. The antisense RNA, IstR-1, is complementary to this site and competes with standby ribosomes for binding. The IstR-1/mRNA interaction generates a cleavage site for RNase III, which results in a 5' truncated *tisB* mRNA that cannot be translated. A variation on this theme has been found for the *E. coli* GcvB sRNA involved in the regulation of amino acid uptake genes. GcvB contains U/G-rich regions that are crucial for binding to upstream ACA trinucleotide translational enhancer elements required for the efficient translation of downstream RBSs. By antagonizing these elements, GcvB can potentially inhibit the translation of multiple target mRNAs containing ACA enhancers, such as *yifK* and *dppA*.

Combined translation inhibition and mRNA degradation Frequently, translation inhibition by a trans-encoded sRNA is found to be accompanied by degradation of the target mRNA by one or more RNases. In some cases, RNase degradation is essential for effective inhibition, as with RNAIII of *S. aureus*. RNAIII is an unusually long sRNA (514nt) composed of 14 stem-loops and two long-distance interactions that define independent structural domains. Among these, three hairpin-loops carry C-rich sequences complementary to multiple RBSs. RNAIII is also an example of a peptide-encoding dual-function sRNA (see below) and can both activate translation of some targets like *hla* and inhibit translation of others, such as *spa*, *sa1000*, and *rot* (Fig. 3). Both *spa* and *sa1000* mRNAs are targeted by a single hairpin loop of RNAIII, whereas *rot* is targeted by two redundant hairpin loops. One loop-loop contact occurs within the *rot* RBS and the other with another stem-loop. Despite the slight differences in target mRNA binding, the subsequent RNAIII inhibitory mechanism is the same: the formation of RNAIII/mRNA hybrid duplexes, inhibition of ribosome binding, and degradation of duplexed RNA by RNase III (Fig. 3). It should also be noted that as a general rule, untranslated mRNAs are less stable than actively translated transcripts, since ribosomes tend to exclude access to endogenous RNase cleavage sites. Thus, translation inhibition and mRNA degradation are frequently coupled events, though not exclusively.

Translation activation For some mRNAs, Shine-Dalgarno (SD) sequences are sequestered within double-stranded secondary structures, which prevent ribosome access and inhibit translation of the transcript. An sRNA can promote the melting of such a structure by forming a hybrid duplex to one strand of the mRNA, thus liberating its complementary strand and RBS. For the aforementioned RNAIII from *S. aureus*, its ability to activate translation of the *hla* mRNA encoding α -hemolysin is due to the remodeling of an endogenous *hla* secondary structure that normally sequesters its RBS within the stem of a hairpin. RNAIII interacts with the anti-SD sequence located in *hla* mRNA to remodel this hairpin and free the RBS for ribosomal loading. A similar mechanism has been demonstrated for DsrA from *E. coli*, which promotes translation of *rpoS* mRNA encoding the stationary phase sigma factor σ^S . Under normal growth conditions, the *rpoS* RBS is sequestered within ~100 nt hairpin that inhibits its

Fig. 3 Overview of regulatory mechanisms employed by trans-encoded antisense RNAs. Antisense RNAs are drawn in red, sense RNAs in blue. Green, regions complementary between sense and antisense RNA, light blue, ribosome binding sites. Black arrows denote RNase III action. Yellow symbols indicate ribosomes.

translation initiation. However, under conditions where DsrA is active, such as low temperature, it can bind to the anti-SD to free the RBS for translation. In contrast to the RNAIII example, the interaction between DsrA and *rpoS* also requires the RNA chaperone Hfq (see below) to catalyze duplex formation.

Dual-function sRNAs and mRNAs While sRNAs are generally regarded as non-coding RNAs, it is now evident that a subset of trans-encoded sRNAs encode actively translated ORFs. These molecules are referred to as dual-function sRNAs and examples can be found in both Gram positive and Gram negative bacteria. The antisense riboregulatory functions of dual-function sRNAs are identical to the aforementioned examples of typical sRNAs (i.e., translation activation or repression, target mRNA stabilization or destabilization, etc.). The distinguishing feature of dual-function sRNAs is simply the presence of their encoded proteins. Thus far, all characterized dual-function sRNAs have been demonstrated to encode peptides ranging in size from 26–53 amino acids, and of these, only several have known functions. Interestingly, these peptides may or may not function within the same pathways targeted by their encoding sRNAs. For example, RNAIII from *S. aureus* was the first recognized dual-function sRNA. The *hld* coding sequence (CDS) within RNAIII encodes the 26 amino acid δ -toxin, which seems to primarily function in the lysis of host cell membranes. The δ -toxin is not known to directly affect any of the pathways targeted by RNAIII. In fact, base pairing interactions between RNAIII and one of its target mRNAs (*hla*) obscures the RBS of *hld*, suggesting that riboregulation by RNAIII and the production of δ -toxin are likely to be uncoupled events. In contrast, the SgrS dual-function sRNA from *E. coli* encodes the 43 amino acid peptide SgrT, which functions independently in the same glucose-phosphate stress response pathway as SgrS. Production of SgrS is triggered by a toxic accumulation of phosphorylated carbohydrates within the cytoplasm. To mitigate this stress, SgrS represses the translation of the *ptsG* and *manXYZ* mRNAs encoding carbohydrate transporters, whereas the SgrT peptide inhibits carbohydrate uptake through preexisting carbohydrate transporter complexes. Another example is SR1 from *Bacillus subtilis*. In addition to its base-pairing function in arginine catabolism (see above) SR1 encodes a small, 39 aa peptide designated SR1P. SR1P binds to GapA, one of the two *B. subtilis* glyceraldehyde-3P-dehydrogenases that participate in glycolysis. In 2016, it was shown that GapA has a moonlighting function in RNA degradation by forming a complex with RNase J1 and the main *B. subtilis* endoribonuclease RNase Y. Interestingly, SR1P modulates the moonlighting activity of GapA. By promoting the interaction between GapA and RNase J1, it can also regulate the activity of RNase J1.

The existence of dual-function sRNAs indicates that riboregulatory RNAs are fully capable of serving as templates for translation like typical protein-encoding mRNAs. Such a function is not unique to prokaryotes, as a variety of riboregulatory RNAs in eukaryotes also encode functional peptides, such as the *ENOD40* RNA from the legume *Medicago truncatula*. Perhaps not

surprisingly, examples of riboregulatory protein-encoding mRNAs also have been reported, which suggests that mRNAs in general should be considered as potential riboregulatory molecules. In the Gram positive organism *Streptococcus mutans*, the *invA* gene encodes a putative transcription regulator that was originally hypothesized to control the expression of a target gene called *gbpC*. Surprisingly, the 5' UTR of *invA* and not its encoded protein was determined to be the principal regulator of *gbpC* gene expression. In this case, the *invA* 5' UTR was shown to bind to the CDS of *gbpC* mRNA and block access to an endogenous RNase cleavage site, thereby preventing *gbpC* degradation and stimulating GbpC protein production. The *invA* 5' UTR was also demonstrated to be functionally modular, since its riboregulation of *gbpC* remained fully intact when the UTR was fused to the CDS of green fluorescent protein (GFP). This result implies that other mRNAs could still have a wild-type riboregulatory function even if the CDS has been mutated. In addition, there are a variety of examples of mRNAs that yield non-coding riboregulatory sRNAs through RNA processing events or via the regulation of transcription termination. For example, both the CpxQ and RybD sRNAs from *S. typhimurium* as well as the MicX sRNA from *Vibrio cholerae* are all produced from RNase E cleavages within the 3' UTRs of mRNAs. For the CpxQ sRNA of *Salmonella*, its parent mRNA *cpxP* encodes a stress chaperone that functions in tandem with CpxQ to reduce the abundance of misfolded proteins in the inner membrane during episodes of membrane stress. While the CpxP protein chaperone is required for degrading misfolded proteins, the CpxQ sRNA post-transcriptionally inhibits the production of a variety of inner membrane proteins to prevent further accumulation of misfolded proteins in the membrane. The regulation of transcription termination is another mechanism to generate sRNAs from mRNAs. In *Listeria monocytogenes*, two S-adenosylmethionine (SAM) riboswitches (SreA and SreB) located in the 5' UTRs of the mRNAs *lmo2230* and *lmo0049* both terminate the transcription of their respective mRNAs in the presence of SAM. Upon termination, the riboswitches are able to serve as sRNAs to reduce the abundance of the *prfA* mRNA, which encodes a critical regulator of virulence genes. This mechanism provides a key regulatory link between the metabolic state of the cell and the production of virulence factors. Transcriptional read-through is an alternative transcriptional mechanism capable of producing riboregulatory sRNAs from protein-encoding mRNAs. In the Gifsy-1 prophage found in species of *Salmonella*, the IsrK sRNA is located immediately upstream of a two-gene operon encoding the ORF45 and AnrP proteins. The transcripts from this operon can exist in two forms. A rho-independent terminator located between IsrK and the downstream *orf45* and *anrP* CDSs creates the short transcript, which is comprised solely of the IsrK sRNA. However, a subset of transcripts can read-through this terminator structure to produce a long transcript that includes both CDSs. Interestingly, the long transcript is translationally silenced by its own endogenous secondary structure and is only able to yield appreciable quantities of protein when directly activated by the IsrK sRNA. Thus, IsrK is riboregulatory for its own mRNA. Given the limited number of examples of dual-function sRNAs and mRNAs, it is still unclear whether translated riboregulatory RNAs are the exception or the rule. However, the fact that such activity can already be observed among a broad diversity of prokaryotes and eukaryotes, it seems likely that mRNA will eventually be recognized as a much more sophisticated molecule than is currently appreciated. It should also be noted that alternative functions of mRNAs are not solely limited to riboregulation. The VegT gene in the model organism *Xenopus laevis* encodes a transcription factor that plays a key role in mesendoderm patterning in developing embryos. In addition to its protein-encoding function, VegT mRNA integrates into the cytoskeleton of *Xenopus* oocytes to provide structural support that is both essential for the integrity of the cytoskeleton and for proper germline development. Thus, translated RNAs are likely to function via a wide variety of currently unrecognized mechanisms that may or may not participate in the same pathways or functions as their encoded proteins.

Role of Hfq

One important hallmark of many trans-encoded antisense RNAs from *E. coli* is their ability to bind the RNA chaperone Hfq. In 1968, Hfq was identified in *E. coli* as a host factor required for the replication of bacteriophage Q β . It is present in half of all sequenced bacterial species. Several bacteria such as *Bacillus anthracis* and *Ralstonia metallidurans* even encode two Hfq proteins. At least one archaeon, *Methanococcus jannaschii*, contains a protein that is related to Hfq. Hfq comprises between 70 and 110 amino acids and forms homohexamers. It is an abundant protein, which is present in up to 60,000 monomers/*E. coli* cell in the stationary phase. The major fraction is associated with the ribosomes, whereas a minor Hfq fraction appears to be associated with the nucleoid. Hfq was shown to bind to AU-rich sequences in single-stranded regions generally flanked by one or two stem-loops. The Hfq homohexamer is very similar to the eukaryotic Sm and Sm-like proteins involved in splicing as well as the archaeal Lsm proteins (Fig. 4A and B). It forms a toroid quaternary structure with an outer diameter of ~ 70 Å and a thickness of 25 Å. The central pore is 8–12 Å wide. The N-terminal α helix is followed by 5 β strands that form a tightly bent sheet (Fig. 4C). Hfq has two primary RNA binding sites for sRNAs and mRNAs, a proximal and a distal (Fig. 4D). The co-crystal structure of the *S. aureus* Hfq bound to an AU₅G oligo shows how the RNA expands and fills the central, basic pore on the 'proximal side' of the hexamer and binds in a circular manner with the exception of the 3' G located at the entrance of the pore (Fig. 4D). Each of the six potential AU nucleotide-binding pockets is composed of residues from two adjacent subunits. The repetition of identical binding pockets on the Hfq hexamer suggests that the binding surface can accommodate more than just a single target, which is particularly important for catalyzing sRNA-mRNA base pairing interactions. Recent studies of the *E. coli* Hfq indicate that it has two binding mechanisms for sRNAs. sRNAs binding by the first mechanism (termed Class I), depend upon sRNA interactions with the proximal and rim sites of Hfq. These sRNAs exhibit rapid turnover and regulate mRNAs containing ARN repeats (A = adenine, R = purine, and N = any nucleotide), which target the mRNAs to the distal face of Hfq. Class II sRNAs primarily interact with the proximal and distal faces of Hfq, while their target mRNAs contain UA-motifs that interact with the rim of Hfq. Class II sRNA interactions tend to result in target regulation in the absence of substantial degradation. Thus, Class II sRNAs have a higher intrinsic stability compared to those of Class I.

In *E. coli*, inactivation of the *hfq* gene causes pleiotropic effects, such as reduction of growth rate, UV sensitivity, and increased cell length. Hfq is involved in mRNA stability, mRNA polyadenylation, and translation. The importance of Hfq is further underscored

could be assigned an *in vivo* function. It was shown to stabilize LhrA and promote the LhrA/target-mRNA interaction. By contrast, for SR1 from *B. subtilis* and RNAIII from *S. aureus*, Hfq is not required for target interactions. Accordingly, Hfq is not highly expressed in *S. aureus*. It cannot be excluded that in the majority of Hfq-encoding Gram positive bacteria, Hfq is needed for other, still unidentified functions. It is also conceivable that other RNA binding proteins might fulfill the role of Hfq in these bacteria, especially for those that do not encode Hfq. One candidate is CsrA (see below) that was recently shown to be bound and sequestered by the trans-encoded base-pairing sRNA McaS in *E. coli*.

Differences between *cis*- and *trans*-encoded antisense RNAs

Cis-encoded RNAs have regions that are fully complementary to their targets over a large nucleotide stretches and can, therefore, spontaneously form stable duplexes with their target RNAs. Consequently, RNA chaperones like Hfq are generally less important to promote their target interactions. Exceptions seem to be Tn10/IS10 and Tn5. For IS10, Hfq was demonstrated to bind and restructure RNA-IN and RNA-OUT to facilitate duplex formation and inhibit transposase translation by binding to the RBS. Similarly, for the plasmids ColE1 and R1/F, plasmid-encoded RNA binding proteins (Rom and FinO, respectively) were shown to further enhance duplex formation. In contrast to most cis-encoded sRNAs, a large number of trans-encoded antisense RNAs have been demonstrated to require Hfq either for protection from RNase degradation or for duplex formation. Presumably, this is because sRNA-target interactions are only partially complementary and likely have less favorable binding kinetics. Another major difference between cis- and trans-encoded sRNAs is the diversity of regulation exhibited by individual sRNAs. Each cis-encoded antisense RNA uses a single defined mechanism of action for an individual target. On the contrary, trans-encoded sRNAs can simultaneously employ multiple mechanisms for multiple target mRNAs. For instance, RNAIII, DsrA, and RyhB inhibit the translation of some targets, yet activate translation of others. Conceivably, a single trans-encoded sRNA might be able to use three or four different mechanisms to regulate various targets.

Trans-Encoded sRNAs That Act via Protein Binding

In contrast to the trans-encoded sRNAs that exert their function by base-pairing interactions with target mRNAs, another class of sRNA employs protein binding as its mechanism of action. Two principal classes of protein-binding sRNAs can be distinguished: 6S RNA that binds RNA polymerase and sRNAs that sequester small proteins inhibiting the translation of target mRNAs. In both cases, RNA binding reversibly inhibits the target protein and results in global changes in gene expression. A potential third class of sRNAs binds to and modulates the activity of enzymes. Thus far, this mechanism has proven to be quite rare and is exemplified by Rcd of the *E. coli* ColE1 plasmid. (Table 3)

6S RNA

6S RNA was discovered in the late 1960s and for more than 30 years its function remained enigmatic. By 2005, it was recognized to be ubiquitous among bacteria. To date, more than 100 putative 6S RNA homologues have been identified in diverse bacteria and many have been confirmed experimentally. In *B. subtilis*, two differentially expressed 6S RNA species exist during growth. 6S RNA has a characteristic secondary structure consisting of a central region with a largely single-stranded internal loop flanked by two long irregular double-stranded stem regions interrupted by small bulges. This secondary structure resembles a partially single-stranded DNA bubble and has led to a hypothesis for the potential function of 6S RNA (Fig. 5). 6S RNA forms a stable complex with RNA polymerase and was assumed to act as an open promoter DNA mimic that interferes with the formation of transcription initiation complexes. Its levels increase ~10-fold to about 10,000 molecules during stationary phase and it interacts preferentially with RNA polymerase holoenzymes containing the exponential phase sigma factor σ^{70} . Based on these observations, it was proposed that 6S RNA participates in shifting global gene expression from exponential to stationary phase. However, there is reason to believe that its

Table 3 Examples of trans-encoded sRNAs acting via protein binding

Fig. 5 Overview of sRNAs acting by protein binding. Red, 6S RNA, brown, RNA polymerase core, yellow and white symbols denote σ^{70} and σ^S , Black and white rectangles indicate -35 and -10 boxes, respectively. (A) Mechanism of 6S RNA action. (B) Mechanism of action of sRNAs binding translational regulators. The RsmA-RsmB regulatory system of *Erwinia carotovora* ssp. *carotovora*. RsmB primary RNA is subsequently processed yielding a 259 nt long functional RNA (RsmB'). Free RsmA protein induces degradation of target mRNA. Binding of RsmA protein to RsmB' depletes the pool of free RsmA thereby inhibiting target mRNA degradation. The binding of RsmA to RsmB' also protects the RsmB' transcript from degradation.

actual function is more complex. 6S RNA is still expressed and functional during exponential phase and its effect upon gene expression is not uniform with some genes affected, while others are not. 6S RNA can also act as a template for the production of small de novo transcripts, which suggests another aspect of 6S RNA function. 14–22nt transcripts (pRNA) were observed when the 6S RNA concentration was high, whereas 170nt transcripts were observed when RNA polymerase (RNAP) concentrations were high. In *B. subtilis*, newly synthesized pRNAs form stable duplexes with 6S RNA, which induce structural rearrangements *in cis* and trigger 6S-1 RNA release from RNA polymerase upon outgrowth from stationary phase, delaying sporulation. Both the generation and the role of the longer transcripts are still unclear. Likewise, the physiological function of 6S RNA is still the subject of debate. While 6S RNA is widely conserved among bacteria, 6S RNA mutants grow normally in laboratory conditions, indicating its function is dispensable under certain growth conditions. However, 6S RNA mutants do exhibit decreased survival during long-term nutrient deprivation.

Small RNAs that act by sequestration of translational regulators

In 1997, it was shown that a small untranslated RNA, CsrB from *E. coli*, does not act via base pairing to an mRNA target, but exerts its function by binding to the small protein CsrA. CsrA is a repressor of stationary phase processes, such as gluconeogenesis and biofilm production, and an activator of glycolysis, motility, and acetate metabolism. For example, CsrA binds to the 5' UTR of the *glgCAP* transcript, where it blocks translation and causes rapid mRNA degradation. In contrast, the activation of gene expression by CsrA involves binding to the 5' UTR to prevent the degradation of transcripts, such as the master operon for flagella biosynthesis *flhDC*. For *flhDC*, CsrA prevents 5'-end dependent RNase E cleavage by binding to two sites within the 5' UTR. Furthermore, CsrA represses ribosome binding to *pgaABCD* mRNA, which is involved in biofilm formation. In addition, it also remodels the *pgaABCD* 5' UTR to unveil *rut* sites for terminator Rho binding, resulting in premature transcription termination. Highly conserved CsrA orthologues are found in diverse eubacteria and regulate virulence factors of plant and animal pathogens. The CsrA/CsrB ribonucleoprotein complex comprises 18 CsrA protein subunits and a single CsrB sRNA. Binding of CsrA to CsrB or target mRNAs involves the same CAGGAUG imperfect repeat sequence that can be found primarily in the loops of the CsrB hairpins. In 2003, a second RNA, CsrC, has been found that acts by binding 9 CsrB molecules. Null mutations of either CsrB or CsrC cause a modest increase in abundance for the other sRNA. The consensus binding motif of the *E. coli* CsrA protein has been identified as 5'-RUACARGGAUGU-3' (R = purine), which naturally forms a stem-loop with an important GGA located within the loop. The GGA sequence can also be found in both CsrB and CsrC as well as CsrA-regulated mRNAs. This motif is recognized on the related RsmY and RsmZ sRNAs from *Pseudomonas fluorescens* as well. These two sRNAs regulate secondary metabolism and biocontrol traits in *P. fluorescens*, such as antifungal metabolites and extracellular enzymes, and are under the control of the two-component GacS/GacA system. An *rsmY/rsmZ* double mutant is strongly impaired in the synthesis of extracellular enzymes, whereas single mutants do not exhibit significant defects.

A similar pathway is present in *Erwinia carotovora*, where the GacS/GacA system promotes expression of the *rsmB* gene (Fig. 5). Homologous elements are also found in *S. typhimurium* where they control the expression of genes related to invasiveness.

A small RNA that acts by binding tryptophanase

The *cer* site is required for the resolution of ColE1 plasmid dimers by the site-specific Xer-*cer* recombination system composed of four proteins, XerC, XerD, ArgR, and PepA. The resolution of plasmid multimers must be achieved before the cell divides, as this is the only time when a plasmid may be lost. Upon induction by plasmid multimers, the untranslated Rcd RNA is transcribed from a promoter within the *cer* site. In 2007, it was discovered that Rcd acts by binding the enzyme tryptophanase (TnpA), increasing its affinity for tryptophan and stimulating indole production by rapidly dividing cells (low density cultures). Indole serves as an intracellular signal molecule by acting as an ionophore that modulate the membrane potential to delocalize FtsZ, FtsA, and MinD, and thus inhibit formation of the divisome. The resulting delay in cell division then gives the plasmid time to convert multimers into monomers.

sRNAs that act as RNA sponges

The sequestration of the translational regulator CsrA by the small untranslated RNA CsrB as well as the association of the 6S RNA with the RNAP/ σ^{70} holoenzyme during the stationary phase are prime examples of how sRNAs are able to direct the regulatory function of a protein away from its original target. A similar observation has been made with RNAs that sequester heterologous sRNAs, thus excluding them from their regulatory target interactions. Such RNAs have been referred to as RNA sponges, RNA traps, competing endogenous RNAs, or RNA decoys. The basic principle is that a regulatory sRNA can be competed away from its intended mRNA target by forming duplexes with sponge RNAs. Consequently, a previously repressed mRNA can once again become available for translation. An sRNA sponge mechanism has been demonstrated in the regulation of the enterobacterial chitoporin ChiP protein required for the transport of chito-oligosaccharides across the outer membrane. Under non-inducing conditions, translation of the *chiP* mRNA is repressed by base-pairing between the ChiX sRNA and the 5' UTR of *chiP* mRNA leading to RNaseE-dependent degradation of *chiP* mRNA. However, a sponge mechanism is activated upon chitobiose induction of the chitobiose-specific phosphotransferase (PTS) system operon (*chbBCARFG*). The intercistronic sequence between *chbB*–*chbC* provides an alternative hybridization site for the ChiX sRNA, sequestering ChiX and relieving the translational repression of *chiP*, eventually allowing for maximal chito-oligosaccharide utilization. Another novel regulation has recently been linked to the 3' external transcribed spacer (ETS) of the tRNA *leuZ*. This sRNA functions by sponging the pool of RyhB and RybB sRNAs transcribed as a result of leaky basal expression from their strong promoters. RyhB and RybB are known to be involved in TCA cycle remodeling, iron homeostasis, envelope stress response, and antibiotic resistance, which highlights their global influence upon bacterial metabolism and stress adaptation. It is intriguing to speculate that the 3' ETS will likely have a similar functional role in other species, since the 3' ETS of *leuZ* exhibits global sequence conservation among the various Enterobacteriaceae. Furthermore, the 3' ETS of certain pre-tRNAs seem to be even more highly conserved than the 3' ETS of *leuZ*, suggesting other uncharacterized regulatory functions likely exist. Another example involves a target mRNA-derived sponge of the sRNA GcvB, which is also widely conserved among Enterobacteriaceae. The decay of *gluJLK* mRNA encoding an amino acid ABC transporter produces a stable RNA fragment designated SroC that base-pairs with GcvB causing its degradation by RNase E. This alleviates GcvB-mediated repression of mRNAs encoding amino acid-related transport and metabolic genes. Interestingly, as *gluJLK* mRNA is itself a GcvB target, the SroC sponge can both activate its own production in cis as well as activate many trans-encoded sRNAs in the same pathway.

Sensory RNAs

Only recently was it demonstrated how RNAs can directly sense environmental conditions and, thus, play a central role in the genetic control of metabolic processes. In the majority of cases, such sensory RNA elements are located in the 5' UTRs of mRNAs where they form complex secondary structures controlling the expression of downstream genes via signal induced conformational changes. Such signals can either be of physical origin (RNA thermometers) or of chemical origin (riboswitches).

RNA Thermometer

RNA thermometers (RNATs) are RNA structures that gradually change their conformation in response to temperature. A conformational arrangement of the RNA structure is able to detect variations as low as 1°C. Most, but not all characterized RNA thermometers are located in 5' UTRs and sequester RBSs by intramolecular base pairing at low temperatures. The temperature-dependent refolding of mRNA secondary structures results in a gradual melting of the double-stranded portion of the inhibitory stem loop(s), thus allowing ribosome access and translation initiation (Fig. 6A). The majority of RNA thermometers participate in the control of heat-shock and cold-shock responses and several regulate virulence gene expression in pathogenic bacteria.

Some of the best-characterized RNA thermometers include the *rpoH* thermometer as well as the ROSE and FourU elements (Fig. 6B), which are involved in the control of heat-shock and virulence gene expression. Expression of the *E. coli* heat-shock sigma factor *rpoH* (σ^{32}) is regulated at the transcriptional, post-transcriptional, and post-translational levels. Transcription is regulated by σ^{32} itself. Translation of *rpoH* is regulated by an RNA thermometer that is composed of two stem-loop segments (I and II in Fig. 6B),

Fig. 6 RNA thermometer. (A). *Regulatory principle of an RNA thermometer.* This principle has been postulated for heat shock and virulence genes. RBS, ribosome binding site, AUG, start codon. 30S and 50S symbolize the ribosomal subunits. Temperature changes are indicated by a color change within triangles (by blue=cooler, and red=warmer). (B). *Secondary structures of three representative RNA thermometers* Right: FourU thermometer from the 5' UTR of the *agsA* gene of *S. typhimurium*. The secondary structure was confirmed experimentally.

which extend into the *rpoH* CDS. Under heat shock conditions, stem-loop I melts allowing ribosomes to access the RBS. Interestingly, the other stem-loops in the CDS also contribute to the thermometer function, since a minimal *rpoH* thermometer composed only of stem-loops I, II, and, V required additional mutations in stem II to maintain heat inducibility. While the *rpoH* thermometer is found only in *E. coli* and its relatives, another RNA thermometer, the ROSE element (Repression Of heat Shock gene Expression) - originally discovered in *Bradyrhizobium* - is widespread in different alpha and gamma proteobacteria. Located in the 5' UTR of genes for small heat-shock proteins, ROSE elements consist of two to four stem loops ranging from 60 to >100 nt. The 3' proximal stem loop comprises the RBS and the AUG start codon (Fig. 6B). In all known cases, a highly conserved G opposite of the RBS has been found to be important for heat induction of the downstream genes. Mismatches and a mixture of canonical and non-canonical base pairs in the RNA thermometer ensures that the reversible melting process occurs within the physiological temperature range between 25°C and 42°C. Another type of RNA thermometer, designated FourU, has been discovered in the 5' UTR of the *S. enterica agsA* gene, encoding a small heat-shock protein. It is composed of only two stem-loops, I and II, the latter of which contains a sequestered RBS that base pairs with 4 U residues in the anti-SD (Fig. 6B). Additional FourU thermometers have been predicted upstream of the *Yersinia pestis lcrF*, *S. aureus groES*, and *Brucella melitensis dnaJ* genes.

Riboswitches

The majority of riboswitches are located in 5' UTRs and regulate in cis the transcription or translation of downstream open reading frames. Riboswitches can detect a variety of signals including vitamins, divalent metals, purines, amino acids, phosphorylated carbohydrates, and charged tRNAs (Fig. 7A and B). They are comprised of an aptamer (i.e., ligand receptor) characterized by a consensus sequence determining its substrate specificity and an output (expression platform) region. Binding of a small molecule results in a conformational switch that alters gene expression by one of three possible mechanisms: transcription attenuation, inhibition of translation initiation, or mRNA cleavage.

The FMN riboswitch is a prominent regulator of riboflavin biosynthesis that responds to cellular pools of FMN (flavin mononucleotide), which is an end product of the riboflavin synthetic pathway. In many species, this riboswitch acts by transcription attenuation, due to the binding of FMN to the 5' UTR of nascent mRNA. In the FMN riboswitch found in the *ribDEAHT* operon of *B. subtilis*, FMN binds to a specific element in the riboswitch called the RFN element, inducing a change in secondary structure that remodels an endogenous antiterminator structure in favor of a transcriptional terminator. However, when FMN concentrations in the cell are low, the riboswitch fails to bind FMN and the 5' UTR adopts an antiterminator structure allowing transcriptional

Fig. 7 Riboswitches. (A). The thiamine-pyrophosphate sensing riboswitch. Depending on the expression platform, the TPP riboswitch acts as a transcription terminator (middle) or as a suppressor of translation initiation (right). The contacts between TPP and the riboswitch sensor domain are summarized on the left side. The TPP binding pocket is formed by two parallel helices: a pyrophosphate binding helix (blue, comprising P4, J4-5, P5 and L5) and a pyrimidine binding helix (red, comprising P2, J3-2, P3 and L3). P1 is only formed in the presence of TPP. TPP is shown in yellow, Mg²⁺ in grey, nonstandard basepairs are in green, and hydrogen bonds are shown by black lines. Light blue (G78) and magenta boxes (G40, G42, A43 and G19) symbolize bases contacted by the pyrophosphate and the pyrimidine moiety of TPP, respectively. Grey boxes indicate the binding sites for the four Mg²⁺ ions. Only the two Mg²⁺ that are involved in the pyrophosphate contact with J4-5 are shown as grey/black circles. The other Mg²⁺ ions are required for folding. TPP binding stabilizes the three-way junction at A72, thus helping the sensor domain to sequester the segment that would otherwise participate in the alternative structure of the expression platform. (B) Overview of known riboswitch classes and their occurrence in selected pathogenic bacteria. The secondary structure models of the receptor domains of 11 riboswitch classes and the chemical structures of the metabolites they bind. The expected protonation states at physiological conditions are shown for each functional group. Three different structural classes of riboswitches have been reported that recognize SAM (*, riboswitch class for which a representative 3D structure has been published). Colored rectangles denote the occurrence of the riboswitch classes in the selected pathogenic bacteria, which are listed below. Thereby, no distinction has been made between the three classes of SAM riboswitches.

read-through. This mechanism is mainly found in low G + C Gram positive bacteria. An FMN riboswitch is also found in the *ribB* gene within the *E. coli* riboflavin biosynthetic locus. In contrast to the *B. subtilis* FMN riboswitch, the *E. coli* version functions largely through a translational control mechanism that involves sequestration of the *ribB* RBS in the FMN-bound state (Fig. 7B). This regulatory mechanism occurs in addition to a weaker antitermination mechanism that proceeds in an analogous fashion to that described for *B. subtilis*. The added layer of translational control was speculated to have evolved to improve upon the sensitivity of the riboswitch, given its relatively modest level of transcription attenuation (~2-fold reduction in gene expression).

Riboswitches that bind FMN, thiamine pyrophosphate (TPP), SAM, vitamin B₁₂, lysine, and guanine have all been found to inhibit gene expression for a wide variety of genes encoding metabolic enzymes. In contrast, the adenine and the glycine riboswitches both work as activators of gene expression via disruption of transcription terminators. The glycine riboswitch is particularly unusual, as it contains two aptamer domains. For sulfur and methionine metabolism, three different riboswitch classes have been identified that contain either an S-box, an S_{MK} box, or a SAM-II box. Fig. 7B gives an overview of various characterized metabolite-sensing riboswitches and their occurrence in a number of pathogenic bacteria. The TPP riboswitch is the most ubiquitous and it is the only one found in eukaryotes, fungi, and plants, where it is involved in intron splicing and mRNA processing/stability.

The 3D structures of several riboswitches have been solved, such as the TPP, adenine, guanine, and SAM riboswitches. The thiamine riboswitch structure revealed how polyanionic RNA is able to both bind a molecule with a negatively charged pyrophosphate group as well as discriminate between TPP and TMP. The structure of the THI-box resembles a tuning fork in which the prongs are formed by two parallel stacking helices (P2, bulge J3-2, loop L3) and (P4, bulge J4-5, and loop L5) arranged via a central three-way junction with helix P1 (Fig. 7A, left). Each of the parallel helices binds to one part of TPP. The pyrimidine part of TPP is bound by bulge J3-2 located in the pyrimidine sensor helix P2-P3 that contains the conserved sequence UGAGA. The pyrophosphate group of TPP is recognized by the J4-5 internal loop present in the pyrophosphate-sensor helix P4/P5, due to an interaction with two Mg²⁺ ions and their corresponding coordinated water molecules. The conformational switch induced by TPP binding is due to TPP forcing the parallel disposition of the pyrimidine and pyrophosphate sensor helices, leading to a kink at the J2-4 junction. This triggers the formation of the P1 helix as well as the formation of a terminator stem or sequestration of the RBS. When the TPP concentration decreases, helix P1 adopts an alternate conformation that forms an anti-terminator hairpin or frees the RBS from sequestration. The purine and SAM binding riboswitches show similar architectures, consisting of three and four helical junctions, respectively.

The first metal ion-sensing riboswitch (Mg²⁺) was discovered in 2006. This riboswitch is located in the 5' UTR of the *mgtA* gene of *S. typhimurium* and can fold into two structures depending upon the cytoplasmic concentration of Mg²⁺. The secondary structure of the riboswitch determines the fate of transcription complexes elongating into the coding region of *mgtA*. It also forms an additional layer of transcriptional control beyond that of the PhoP/PhoQ Mg²⁺ sensory system. The Mg²⁺-bound state induces premature termination of *mgtA* transcription, or in some cases, transcription pausing followed by RNA polymerase release from the template. At sub-micromolar Mg²⁺ concentrations (i.e., low Mg²⁺), the unbound riboswitch adopts an alternate conformation that permits transcriptional read-through, leading to MgtA synthesis. Metalloregulatory riboswitch RNAs are widespread in bacteria and are able to bind divalent metal ions such as Co²⁺, Mn²⁺, and Ni²⁺. In addition, an ion-responsive riboswitch able to detect fluoride has been described in Gram positives and Gram negatives and has been demonstrated to aid in the response to toxic levels of heavy metals.

Other Small RNAs With Diverse Functions

In addition to the large class of regulatory antisense RNAs and riboswitches, a few other non-coding regulatory RNAs with diverse functions exist in bacteria. Among them, are the tmRNA involved in translation quality control, the RNaseP ribozyme required for pre-tRNA processing, the 4.5S RNA portion of the signal recognition particle, and the CRISPR-CAS systems involved in bacterial immunity (Fig. 9). These RNAs act in concert with proteins and will be briefly discussed below.

tmRNA

The 363 nt transfer-messenger RNA (tmRNA) performs translational surveillance and ribosome rescue in all eubacteria by recognizing aberrant mRNA molecules lacking stop codons. The tmRNA, also known as 10Sa RNA or SsrA RNA, is unique because it combines the properties of both a tRNA and mRNA in a single molecule, ensuring that stalled ribosomes complete the translation cycle and are recycled for subsequent use. The tmRNA associates with small protein B (SmpB), elongation factor Tu (EF-Tu), and ribosomal protein S1 to form an active ribonucleoprotein complex. tmRNA and SmpB are essential in several species and involved in pathogenesis in species like *S. enterica* and *Yersinia pseudotuberculosis*. Although tmRNA was discovered in 1978, it was only in 1994 that it was recognized its 5' and 3' ends could fold into a structure resembling the tRNA^{Ala} acceptor stem and T-Ψ-C stem loop (Fig. 8A), while it was also shown to bind alanine in vitro. In 1995, it was found that a heterologous protein expressed in *E. coli* yielded incomplete proteins of varying size sharing the same 11-aa C-terminal extension, AANDENYALAA. The last 10 of these amino acids corresponded to a portion of a short ORF within the *ssrA* gene encoding tmRNA, whereas the peptide tag was missing in an *ssrA* deletion strain. Initially, the tmRNA acts as a tRNA and is aminoacylated with alanine. With the help of EF-Tu and the SmpB C-terminal tail, the aminoacylated tmRNA^{Ala} is delivered to stalled ribosomes on aberrant mRNAs lacking stop codons.

Fig. 8 tmRNA. (A) Proposed secondary structure of *E. coli* tmRNA. The tRNA- and mRNA-like properties are highlighted, including amino acid acceptor stem (AA-stem with G-U wobble base pair), the D-loop and T-arm. The mRNA domain is shown in purple with the conserved UAG and GCA resume signals, the peptide tag coding and amino acid sequence and the UAA stop codon. PK1 to PK4 represent the four pseudoknots drawn in grey. Based on Dulebohn et al., 2007. (Continued)

The ribosome accepts the tmRNA^{Ala} and transfers the nascent peptide followed by the releases of the aberrant mRNA transcript from the ribosome. RNase R will subsequently degrade the mutant mRNA. Next, the tmRNA functions as an mRNA template and the ribosome resumes translation of a short 10-codon ORF encoded by the tmRNA. The tmRNA ORF encodes the SsrA peptide tag as well as a stop codon to complete translation of the defective protein. The encoded C-terminal SsrA tag targets the protein for proteolysis by cellular proteases. As a last step, the tmRNA and the ribosomal subunits are recycled for additional cycles of translation (Fig. 8B). Although tmRNAs are ubiquitous and use the same mechanism of action, the hydrophobic tags they encode differ in length between different bacterial species.

RNase P

Ribonuclease P (RNase P) is an endoribonuclease responsible for the maturation of the 5' end of tRNA in almost all known organisms. Bacterial RNase P is a ribonucleoprotein complex consisting of a large RNA subunit ranging from 340 to 420 nt as well as a small protein subunit (RnpA). The RNA portion of RNase P is a ribozyme that is responsible for the ribonuclease catalytic activity and requires Mg²⁺ for catalysis and proper folding. In vitro, the RNA component alone can process RNA, albeit with reduced efficiency, but the RnpA protein component is essential for in vivo function. RNA secondary structure comparisons have identified three distinct types of prokaryotic RNase P molecules: the most-widely distributed are class A (for ancestral), class B (for *Bacillus*) types, and class C (for *Chloroflexi*), which is the least common and seems to be intermediate between classes A and B. The core structure of bacterial RNase P contains two domains, named C- and S-domains. While the C-domain catalyzes pre-tRNA cleavage, the S-domain and RnpA provide substrate affinity/specificity, recognizing both the D- and TψC-domains of pre-tRNA.

Fig. 8, Cont'd (B) *Trans-translation mechanism.* Ribosomes are drawn in grey, mRNA in blue, tRNA in black and tmRNA in red. Colored boxes symbolize the nascent peptide chain. Amino acids are shown in the 1-letter code. For explanations, see text.

4.5S RNA of the Signal Recognition Particle Pathway

Protein targeting to bacterial plasma membranes for secretion can follow several pathways. Among them is the co-translational pathway, which combines the targeting and translocation process into a coupled step with ongoing peptide synthesis by the ribosome. The universally conserved ribonucleoprotein complex SRP (signal recognition particle) plays an essential part in the co-translational pathway by identifying ribosomes with exposed signal peptides that are subsequently targeted to the protein-translocating channel SecYEG via FtsY. In prokaryotes, the complex consists of the small GTPase Ffh and the 4.5S RNA. The 4.5S RNA plays an essential role in every aspect of the translocation process from the recognition of the signal peptide, the interaction with the ribosome, as well as the efficient targeting and translocation process.

CRISPR-CAS Role in Bacterial Immunity Against Heterologous DNA and Alternative Post-Transcriptional Gene Regulation

The ecological pressure of bacteriophages and other mobile genetic elements able to infect bacterial cells has led to a remarkable small RNA-dependent adaptation mechanism conferring heritable immunity against heterologous DNA. The CRISPR (clustered, regularly interspaced, short, palindromic repeats) - CAS system (CRISPR-associated) is found in about 40% of all sequenced bacterial genomes and in the majority of sequenced Archaea. It provides sequence-specific recognition of foreign genetic elements

with subsequent cleavage and inactivation of the target sequence. The central genomic component is the CRISPR locus encoding small targeting CRISPR or crRNA templates that associate with CAS proteins. The crRNA-CAS complex is able to survey the cytoplasm and hybridize to complementary sequences present in invading DNA. Nucleolytic activity of the CAS protein results in target cleavage, thus inactivating potentially harmful foreign DNA. The CRISPR locus consists of alternating spacer- and repeat-sequence arrangements. Each spacer sequence represents a match to a DNA segment of a bacteriophage or conjugative plasmid previously encountered by the cell or its ancestors. In *Streptococcus pyogenes*, the CRISPR-CAS locus encodes 4 *cas* genes (*cas9*, *cas1*, *cas2* and *csn2*) as well as a small trans-activating RNA called *tracrRNA*. Immediately downstream of the *cas* genes, a variable, strain-specific collection of CRISPR repeats and intervening spacers comprise the CRISPR locus. In the initial step of adaptation, immunological memory is acquired through the stable integration of heterologous proto-spacer DNA that is identified and generated by the Cas1-Cas2 complex in the CRISPR locus. During the expression and maturation stage, the CRISPR locus is expressed as a single precursor-crRNA containing all of the spacers and repeats. During maturation, a ribonucleoprotein complex is formed with the *tracrRNA*, crRNA, RNase III, and RNA-guided DNA endonuclease Cas9. The *tracrRNA* is complementary to the CRISPR repeats found in the crRNA precursor and forms double-stranded (ds)RNA that can be cleaved by RNase III, releasing each crRNA spacer from the precursor. Cas9 and the individual crRNA spacers remain associated in one ribonucleoprotein complex. During the interference stage, this complex is able to scan DNA for the presence of a Protospacer Adjacent Motif or PAM (nucleotides 5'-NGG-3' in *S. pyogenes*), which is found directly downstream of the target sequence. If the crRNA spacer exhibits sufficient homology to the target sequence found upstream of the PAM, Cas9 will cleave between the small crRNA spacer and the target sequences leading to the degradation of the target nucleic acid, thus providing immunity against the invading DNA (Fig. 9).

The regulatory role of the CRISPR-Cas system is not restricted to bacterial immunity against heterologous DNA. Immune evasion by the Gram-negative intracellular pathogen *Francisella novicida* has been linked to a unique small RNA located between the *cas* genes and the crRNA array, named *scaRNA* (small, CRISPR-Cas-associated RNA). When present in the phagolysosome of macrophages, an environment inflicting substantial envelope stress, expression of the CRISPR-Cas system is enhanced. An RNA-protein complex is formed containing Cas9, *tracrRNA*, and *scaRNA* that is capable of targeting the endogenous bacterial lipoprotein (BLP) mRNA. *scaRNA* and *tracrRNA* form a dsRNA, which is believed to stabilize the *tracrRNA* to facilitate its interaction with the BLP transcript. As a result, the amount of BLP mRNA is drastically reduced, possibly through either Cas9 cleavage or the recruitment of another cellular RNase. Since BLP is a substrate for TLR2 activation, its reduced abundance decreases pro-inflammatory cytokine production and promotes innate immune evasion. In addition, another CRISPR-CAS associated small RNA, *nilD* found in the bacterium *Xenorhabdus nematophila* has been demonstrated to play a role in the mutualistic colonization of host nematodes,

Fig. 9 CRISPR-CAS. General overview of the prokaryotic adaptive CRISPR-CAS immune system. In the acquisition step, a short fragment of heterologous DNA (protospacer) processed from the chromosome of a virus or plasmid DNA by the CAS proteins is acquired and integrated into the host CRISPR locus right upstream of the leader (L). The CRISPR locus is comprised of short direct repeat sequences (black blocks) that separate similarly sized spacer sequences (colored blocks). During the expression step, the CRISPR locus is transcribed as a single RNA and subsequently processed to mature crRNAs specific for different sequences. In the silencing step, the crRNA-Cas9 protein complex recognizes foreign DNA through base-pairing of the crRNA with the target sequence. The heterologous DNA is subsequently destroyed, thus providing immunity against the invading DNA.

presumably through its ability to regulate *X. nematophila* gene expression. Thus, there is accumulating evidence that CRISPR-CAS systems play critical regulatory functions in the cell in addition to their better-characterized role in immunity against foreign DNA.

Do RNA Modifications Play a Role in sRNA Regulatory Functions?

Recently, there has been an increasing interest in the role of RNA modifications in determining RNA functionality. Over 140 different modifications have been described thus far and it is conceivable that post-transcriptional regulation is influenced by the modification of either target mRNAs or regulatory sRNAs. While bacterial mRNA modifications have been known for some time and efforts have been made to detect transcriptome-wide RNA modifications, there is still little known about the occurrence and consequences of sRNA modifications. A global transcriptomic survey of N⁶-methyladenosine (m⁶A), one of the most common RNA modifications, identified 15 modified sRNAs in *E. coli* and 2 sRNAs in *P. aeruginosa*. Presumably, additional modified sRNAs still await discovery in both species, as sRNA expression is context-dependent and only one RNA modification was covered in the study. Therefore several questions remain to be answered: i) How widely distributed are sRNA modifications in prokaryotes? ii) What types of modifications are present? iii) Is a particular sRNA uniquely associated with a certain type of modification, or can this vary depending upon environmental conditions? iv) Are sRNA modifications dynamic or static? And most-importantly, v) What are the regulatory implications of sRNA modifications? This is currently a newly developing area of regulatory RNA research that will presumably reveal a variety of new facets to our mechanistic understanding of regulatory RNAs in the coming years.

HCoV	Human coronavirus
HMPV	Human metapneumovirus
HRSV	Human respiratory syncytial virus
HRV	Human rhinovirus
ICU	Intensive care unit
LRTI	Lower respiratory tract infection
RT-PCR	Reverse transcription polymerase chain reaction
SARS	Severe acute respiratory syndrome
URTI	Upper respiratory tract infection
WHO	World Health Organization

Introduction

Respiratory viruses are the leading cause of disease in humans, worldwide. While severe morbidity from respiratory virus infection occurs mostly in children, there is risk to healthy adults, the aged and immunocompromised as well. A wide range of virus families are able to infect and cause disease through the respiratory tract, and generally there is little treatment available other than supportive care. There is a critical need for understanding pathogenesis of infection and the development of therapeutics for this wide-ranging category of viruses.

Most common respiratory viruses cause mild cold symptoms in healthy individuals, resulting in significant loss of productivity. The recently emerged severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV) demonstrate the ability for zoonotic emergence. Owing to the ability to spread via the respiratory route, newly emerging pathogens such as these have the potential for pandemic spread. By increasing our knowledge of these pathogens, we will be able to develop approaches to protect against the common cold and more severe, potentially pandemic, reparatory diseases.

Respiratory Syncytial Virus

The Virus

Human respiratory syncytial virus (HRSV) was first isolated from chimpanzees in 1956, and subsequently from infants suffering severe lower respiratory tract disease the following year. The virus is now recognized as a leading cause of childhood respiratory tract infection across the globe. By age 3, nearly all children will have been infected by the virus. HRSV is a member of the *Orthopneumovirus* genus within the family *Pneumoviridae* of the *Mononegavirales* order. Viruses within the *Mononegavirales* order have a nonsegmented, negative sense, single stranded RNA genome (Table 1). The HRSV genome is approximately 15.2 kilobases in size, comprising 10 genes, which encode 11 proteins (for a schematic view of the genome organization, see Fig. 1). HRSV virions are pleomorphic particles, with either spherical or filamentous forms, around 120–200 nm in size. Virions are encased in a host-derived lipid bilayer, from which three viral proteins protrude; F, G and SH. Within the virion, the genome is bound to the viral nucleoprotein (N) in a ribonuclear protein (RNP) complex. Similar to other negative sense RNA viruses, HRSV particles carry an RNA-dependent RNA-polymerase (L). The virion also contains the phosphoprotein (P) and the matrix protein (M2-1).

HRSV has two glycoproteins involved in cellular entry, F and G. G is responsible for receptor binding, but infection is possible in the absence of this protein, albeit it at lower efficiency. F is a type I fusion protein and is essential for infection. The precise cellular receptor for HRSV has been debated, with heparan sulfate been suggested for many years. More recent work has suggested that this receptor was an artifact of working with immortalized cell lines, and that the receptor on more physiologically relevant human airway epithelial cells is the chemokine receptor CX3CR1, which is found exclusively on the apical surface of

Table 1 A comparative table of the major features of the viruses discussed in this article

Virus	Family	Genome type	Genome size	Virion structure	Major clinical disease
RSV	<i>Pneumoviridae</i>	–ssRNA	15.2 kb	120–200 nm, enveloped	Bronchiolitis, wheezing
HMPV	<i>Paramyxoviridae</i>	–ssRNA	13 kb	150–200 nm, enveloped	URT symptoms
HPIV	<i>Paramyxoviridae</i>	–ssRNA	15 kb	150–200 nm, enveloped	Croup, bronchiolitis
HRV	<i>Picornaviridae</i>	+ssRNA	6–7 kb	30 nm, nonenveloped	URT symptoms
LP-HCoV	<i>Coronaviridae</i>	+ssRNA	27–32 kb	120 nm, enveloped	URT symptoms
SARS-CoV & MERS-CoV	<i>Coronaviridae</i>	+ssRNA	27–32 kb	120 nm, enveloped	LRT, ARDS
AdV	<i>Adenoviridae</i>	dsDNA	35 kb	90 nm, nonenveloped	URT, conjunctivitis, gastroenteritis, myocarditis

RSV, respiratory syncytial virus; HMPV, human metapneumovirus; HPIV, human parainfluenza virus; LP-HCoV, low pathogenicity coronaviruses (HCoV-229E, -OC43, -NL63, -HKU1); SARS-CoV, severe acute respiratory syndrome coronavirus; MERS-CoV, Middle East respiratory syndrome coronavirus; AdV, adenovirus; URT, upper respiratory tract; LRT, lower respiratory tract; ARDS, acute respiratory distress syndrome.

Fig. 1 Schematic representation of genomes of respiratory viruses. The genomes of the discussed respiratory viruses are displayed with approximate size of the viral gene features. The genome features of each virus are color coded with red for viral polymerase, blue for structural/envelope associated proteins, and yellow for replication factors and viral genome associated proteins. For coronavirus genomes, the 5' two-thirds are similar however the 3' one-third is unique to each family, as noted. The green gene products denote virus specific genes unique to each coronavirus species with HCoV-229E as an example of the seasonal coronavirus family. *ITR*, inverted terminal repeats; *IRES*, internal ribosome entry site; *RdRp*, RNA-dependent RNA polymerase.

these cells. The precise trigger for F-mediated membrane fusion is unknown, but is pH-independent because when F is expressed at the plasma membrane of cells it can cause syncytia formation at neutral pH. This syncytia formation is characteristic of HRSV infection and is from where the virus' name is derived. HRSV is generally thought to fuse with the plasma membrane, although there have also been suggestions that the virus is internalized through macropinocytosis prior to fusion with an endosomal membrane. Once membrane fusion is completed the viral genome is deposited to the cytosol. The negative sense RNA genome is transcribed by the actions of the L, P, N and M2-1, giving a set of mRNAs to direct the synthesis of viral proteins. The viral mRNAs are produced in a gradient with decreasing amounts of transcript to the 3' end of the genome. The genes transcribed from the 5' end at the highest abundance are the nonstructural proteins NS1 and NS2 that function to suppress the innate immune response of the infected cell. Over time, the polymerase complex switches from producing mRNA transcripts to producing full-length copies of the viral genome, the antigenome. This switch is in part regulated by the M2-2 protein. The antigenome is used as a template to direct replication of the negative sense genome that associates with N to form the RNP complex. Progeny virions

assemble at the plasma membrane through an interaction of M with the RNP complex and the viral glycoproteins, prior to budding and release. In polarized epithelial cells virion release is directed toward the apical plasma membrane (for a schematic view of the life cycle, see Fig. 2).

Along with directing viral entry into cells, F and G are the main proteins presented to the immune system. HRSV is divided into two serotypes, group A and B, largely based on differences in the G protein, and the differing antibody responses this produces. Within these serotypes there are various genotypes. Group A has 11 genotypes, GA1–7, NA1, NA2, SAA1 and ON1, while group B has 23 genotypes, GB1–4, SAB1–4, URU1, URU2, BA1–12 and THB. Both serotypes and multiple genotypes have been found to co-circulate, although often one serotype will be dominant in a given season. It is thought this genetic and serological diversity is a major reason for the abundance of re-infection throughout life and lack of prolonged immunity.

Fig. 2 A schematic view of the life cycle of the four major viral families that cause respiratory diseases. (A) *Paramyxoviridae* and *Pneumoviridae* have very similar replicative life cycles and illustrated is a view of the HRSV replication life cycle. (1) HRSV attaches to cell surface receptors and has pH-independent fusion. It is generally thought that HRSV fusion occurs at the cell surface, but may also be within endosomes. Some members of the *Paramyxoviridae* have receptor-mediated endocytic uptake and fuse at internal membrane sites (as is depicted in the *Coronaviridae* life cycle). (2) Following release of the negative sense RNA genome to the cytosol, positive sense RNA is produced for protein production and genome replication. (3) Viral proteins are produced, with soluble proteins in the cytosol and the membrane interacting glycoproteins being synthesized at the endoplasmic reticulum (ER). (4) Glycoproteins are trafficked from the ER to the plasma membrane. (5) Viral structural proteins and genomic material associate with glycoproteins at the plasma membrane. (6) Nascent virions bud from the plasma membrane. (B) (1) *Picornaviridae*, such as HRV, bind to cell surface receptors and trigger endocytic uptake. (2) Virions are delivered to endosomes and release their genomes into the cytosol. (3) The positive sense RNA is used to produce viral proteins. Not depicted, the positive sense RNA is used as a template to produce an antigenome which is used for replication of genomic RNA. (3) New viral particles are formed on intracellular double membrane compartments. (4) Viral particles are released from the cell through lysis. (C) (1) *Coronaviridae* are internalized to cells through receptor-mediated endocytosis or have direct fusion at the plasma membrane following proteolytic cleavage of the spike glycoprotein. (2) Cathepsins in acidified endosomal compartments cleave spike to promote membrane fusion to release genomic material to the cytosol. (3) New viral proteins are produced, and the viral genome is replicated similarly to other positive sense RNA viruses. (4) Soluble viral structural proteins and the glycoproteins assemble new virions on membranes in the ER-Golgi intermediate compartment (ERGIC). The new virions that are produced bud into these vesicles. (5) Virus containing vesicles leave the cell through the exocytic pathway to release virus to the extracellular space (6). (D) *Adenoviridae* are taken into cells through endocytic mechanisms. (2) Virus particles are released from the endosome and a partially uncoated virus associates with the microtubule network through dynein motors to traffic to the nucleus. (3) Final viral uncoating occurs at nuclear pore complexes. (4) Double stranded DNA is released into the nucleus and treated similarly to cellular DNA to produce new viral proteins. (5) Viral particles assemble in the nucleus and are released by cell lysis (6).

Epidemiology

HRSV is the leading cause of lower respiratory tract infection (LRTI) in children across the globe. Moreover, pneumonia is the leading cause of mortality in children with HRSV being the most common single cause. Estimates suggest that each year there are over 30 million HRSV infections and over 60,000 childhood deaths worldwide. Approximately 99% of HRSV-associated deaths are in developing countries. HRSV has annual seasonal outbreaks in winter/early spring in temperate regions and during the rainy seasons of tropical regions. The peak of spread in temperate climates is during mid-December until early February. Along with changing climactic conditions and the influence this has on behavior (e.g., increased indoor crowding), protective antibodies may influence the seasonality of HRSV infection. It has been suggested there is a 6 month waning period of protective antibodies, leading to susceptibility come the following season.

It is estimated that around 30% of infants infected with HRSV require medical attention, with 2%–3% of these cases needing hospitalization. Bronchiolitis is the most common cause of hospitalization. Bronchiolitis occurs in roughly 10% of newborns within the first year of life, with between 60% and 90% of cases being due to HRSV infection.

HRSV is predominantly transmitted through close contact, either in the form of large aerosol particles, or through contaminated surfaces and fomites. The virus is stable on hands for half an hour or more, and up to 5 h on surfaces. Following initial contamination, there is usually a 4 to 6 day incubation period, although this can be between 2 and 8 days.

Pathogenesis and Clinical Features

The clinical manifestation of HRSV infection ranges from mild upper respiratory tract infection (URTI), often with otitis media, to more severe LRTI. Approximately a third of patients infected with HRSV will progress to LRTI. The most common presentation of LRTI in infants is bronchiolitis, but pneumonia and croup are also seen. The virus replicates in epithelial cells throughout the respiratory tract causing necrosis of ciliated cells, syncytia formation, peribronchiolar inflammation and impairment of secretion, all of which play a role in airway obstruction and lung hyperinflation, typical of bronchiolitis. HRSV infection is particularly severe in infants because their under-developed lungs are unable to compensate for the damage induced by viral replication and the inflammatory response. Re-infection usually displays reduced severity of disease. In healthy adults, infection usually causes mild, nonspecific features of viral URTI, such as coryza, sore throat, fever and malaise. In the elderly, immunocompromised or those with underlying health conditions, the symptoms are often more severe.

Many factors associated with risk of infant hospitalization have been found such as preterm birth, chronic lung disease, congenital heart disease, low birth weight, acquired or congenital immunodeficiency along with others. However, around half of infants hospitalized by HRSV infection are otherwise healthy. To date, very few protective factors have been found, although breast feeding, and the level of maternally derived antibodies correlate with a decreased likelihood of hospitalization. There is debate over whether there are any viral determinants of disease severity. Various studies suggest that serotype A viruses are more virulent, while others suggest serotype B causes more severe disease. Other studies show no particular impact of viral serotype on disease severity. However, it is established that a higher viral load is associated with increased risk of severe disease; a higher viral load on day 3 of hospitalization was found to be associated with an increased risk of admittance to the intensive care unit (ICU) and respiratory failure.

The immune response has been found to play a role in disease severity. A skew toward a Th2 cytokine response leads to more severe disease. This appears to have been responsible for the failure of a HRSV vaccine trialed in the 1960s. The formalin-inactivated vaccine designed to provide protection actually exacerbated the symptoms of circulating HRSV infection with 80% of recipients to be hospitalized, resulting in two deaths. One suggestion for the enhanced severity was that the vaccine promoted a Th2 response upon subsequent natural infection, whereas a primary infection by circulating HRSV and subsequent re-infection would be skewed toward producing a Th1 response.

Finally, there have been suggestions that HRSV hospitalization is associated with long-term sequelae. Infants hospitalized by HRSV infection have been suggested to have an increased likelihood of developing persistent wheezing, exacerbations of asthma and in some cases develop inflammatory airway disease.

Diagnosis

Nasopharyngeal aspirates, nasal washings, swabs and lower respiratory tract samples can all be used for viral detection. From these samples, virus can be recovered from various immortalized cell lines. Most commonly used are HEp-2, although other epithelial derived cells such as HeLa and A549 can also recover virus. All culture methods have a 3 to 7 day turnaround time so are not suitable for diagnostics.

Rapid antigen detection tests (RADT) have been developed such as enzyme-linked immunosorbent assays (ELISA) and chromatographic immunoassays (CIA). These are both easy to use and have a rapid (under 10 min) turnaround time making them applicable at the point of care. Immunofluorescence assays can also be used from sloughed respiratory cells collected from a patient. This approach is slower than the RADTs but has a higher degree of sensitivity.

Overall, the most common, and sensitive, diagnostic tool is reverse transcription polymerase chain reaction (RT-PCR). Using real time methods, RT-PCR can be used to generate quantitative results to assess viral load as well as detect the virus. As discussed

previously, high viral load is associated with increased disease severity, so assessing viral load may be beneficial to judge likelihood of severe disease developing.

Management and Control

Currently, the majority of HRSV infection treatment is supportive. Most national recommendations emphasize the need for appropriate delivery of supplemental oxygen and hydration, in cases requiring treatment. The treatment of bronchiolitis is more extensive, but again supportive. Bronchodilators can be used such as alpha- and beta-adrenergics, anticholinergics and nebulized epinephrine, however, there is no conclusive evidence that these have a positive impact on disease outcome. Aspiration of respiratory secretions, or mechanical ventilation can be used to prevent hypoxemia, and in the most severe cases, extracorporeal membrane oxygenation can be used.

Ribavirin is currently approved for treatment of HRSV infection, but there is limited evidence for efficacy with meta-analyses suggesting that the investigations performed have lacked appropriate sample sizes to draw firm conclusions. The lack of conclusive evidence regarding efficacy, coupled with the side effects associated with ribavirin treatment means the drug is only administered to infants at the highest risk of severe disease. Ribavirin use in adults is off-license and limited to severely immunocompromised patients.

Passive immunization with humanized monoclonal antibodies is currently the most effective means of control for HRSV infection but its use is limited due to cost. Palivizumab is a monoclonal antibody (mAb) that targets the F protein of HRSV to block infection. The mAb is administered prophylactically by monthly intramuscular injection through the HRSV season in infants at highest risk of severe disease (5 monthly injections). A second generation mAb, Motavizumab, was developed but found to be no more efficacious than Palivizumab. Other companies have worked on the development of mAb therapy; Suptavumab went to a phase III clinical trial but was discontinued when primary end point measures were not met, and MEDI8897 is currently undergoing clinical development. Additionally, the approach of using nanobodies to target the F protein is under clinical development.

Vaccination would be the gold-standard for prophylactic protection, and has been long sought after, although hampered by the initial attempts. As discussed previously, in the 1960s a formalin-inactivated vaccine against HRSV was trialed in infants, but discontinued as it was found to enhance disease severity. This outcome has limited the development of an appropriate HRSV vaccine ever since. Other factors compound the issues of vaccine development; the vaccine would need to be administered at a very young age when the immune system is poorly developed, maternal antibodies may interfere, natural infection does not provide durable immunity, and it is unethical to test the vaccine efficacy in the appropriate target population of newborns/infants. However, much work is going into the development of an HRSV vaccine with four categories of vaccine being investigated; live-attenuated vaccines, subunit vaccines, vector-based vaccines and particulate vaccines.

In addition to work toward developing a vaccine to target HRSV, much effort is being placed in the development of antiviral compounds. Many different small molecules targeting various aspects of the viral life cycle are under development. Many fusion inhibitors are being trialed, along with compounds that target the G attachment protein, the L polymerase function (nucleoside and nonnucleoside inhibitors), the viral mRNA guanylation activity of the L protein and inhibitors of the N protein.

In summary, currently, the majority of treatment for severe HRSV infection is supportive toward the respiratory symptoms caused by viral infection. Monoclonal antibody therapy appears to be effective, but its use is limited by cost and the need for monthly injections, making it unviable in the developing countries where 99% of HRSV-associated deaths occur. Various antiviral compounds and vaccine strategies are being trialed, but at the time of this writing, none have been approved for use in humans.

Human Metapneumovirus

The Virus

Human metapneumovirus (HMPV) is a negative sense, single stranded RNA virus of the *Pneumoviridae* subfamily within the *Paramyxoviridae*. It was first isolated in 2001 in the Netherlands through analysis of samples from children with respiratory tract infection of unknown etiology. HMPV is now recognized as the second most common cause of LRTIs in children after HRSV, which is in the same viral order (*Mononegavirales*). Retrospective studies have found HMPV to be present in the human population for at least 50 years. The virus can be divided into two serotypes, A and B, based on alleles of the surface proteins.

The approximately 200 nm diameter viral particles of HMPV are enveloped and infect epithelial cells in the nose and lungs (Table 1). Overall, replication of HMPV is similar to that previously described for HRSV. Infection proceeds through the attachment of glycoprotein (G) to heparan sulfate and other glycosylated proteins. The fusion (F) protein then interacts either with integrins or a currently unknown receptor to induce endocytosis. The F protein is activated by low pH in endosomal compartments to promote fusion between viral and cellular membranes for release of genetic material to the cytosol. The negative sense RNA genome is then used to direct production of new viral particles, which bud from the plasma membrane, as described previously for HRSV.

Epidemiology

HMPV is associated with approximately 20% of respiratory tract infections in children worldwide. Serologic surveys show that by 5–10 years of age, between 90% and 100% of children have been infected by HMPV. The median age of initial HMPV infection is close to 12 months of age, older than HRSV.

HMPV infections mostly occur in late winter and early spring, generally following the influenza and HRSV season. Infection causes mild URTI in healthy children and adults, however in the immunocompromised and elderly, severe symptoms are commonly observed. Despite the seroprevalence of HMPV in young children, re-infection is common due to either insufficient antibody generation or infection with a different serotype.

Pathogenesis and Clinical Features

The clinical features of HMPV infection are similar to those presented during an HRSV infection, causing mild upper, or severe lower respiratory tract infections. Studies in humans have found diffuse alveolar damage, sloughing of epithelial cells, eosinophilic cytoplasmic inclusions, syncytia and hyaline membrane formation. Common symptoms are fever, cough, tachypnea, dyspnea, hypoxia, rhinitis and sore throat. It has been reported that approximately 50% of infants present with otitis media. Hospitalization from HMPV infection is most common in infants aged 6–12 months, with bronchiolitis and pneumonia being the most frequent causes. Higher viral load is significantly associated with disease severity. Infection inhibits the immune response which can delay clearance of the virus from the respiratory tract and is probably the reason for low level neutralizing antibody development.

Diagnosis

Detection of HMPV is by RT-PCR from nasal or throat swabs. Serum from patients can also be tested. Virus from nasal secretions can be grown in cell culture and immunofluorescence used for detection.

Management and Control

Virus transmission is through respiratory secretions and contaminated surfaces. As such, spread can be limited by general hygiene countermeasures. No treatments are licensed although ribavirin has been used in severe cases. No clinical trials have been performed to examine the efficacy of ribavirin in humans, but it has been shown to be effective in vitro and in mouse models of infection. As previously discussed, monoclonal antibody therapy is used for HRSV infection and therefore may have potential for protection against HMPV infection, although this is at an early stage of development. Monoclonal antibodies have been shown to be protective in mouse, hamster and cotton rat models of infection, but have yet to be thoroughly examined in humans. Fusion inhibitors and RNAi approaches are also being explored. There is no HMPV vaccine, although similarly to HRSV, multiple approaches are being explored. Currently, palliative care is recommended to allow for clearance of the virus and recovery from the respiratory inflammation resulting from infection. Oxygen therapy, corticosteroids and mechanical ventilation can all be used for symptomatic treatment.

Human Parainfluenza Virus

The Virus

Human parainfluenza viruses (HPIV) are nonsegmented, negative sense, single stranded RNA viruses of the *Paramyxovirus* genus (like HMPV). HPIV was discovered in the 1950s as the cause of LRTI in children that were not the result of the already known influenza virus. Based on genetic and antigenic diversity, HPIV is divided into four types, HPIV-1, 2, 3 and 4, with HPIV-4 having subtypes a and b. These types are further subdivided into the respiroviruses, HPIV-1 and HPIV-3, and the rubulaviruses, HPIV-2 and HPIV-4.

The genome of HPIV is a single, negative sense strand of RNA of approximately 15 kilobases in a pleomorphic enveloped virion that ranges from 150 to 200 nm in diameter (Table 1). The virion envelope contains a glycoprotein that has both hemagglutinin and neuraminidase enzymatic activities (HN protein). HN is involved in entry of the virion via attachment of the hemagglutinin to sialic acids on the surface of permissive cells. Entry for HPIV occurs at the plasma membrane when the fusion protein (F) is cleaved by surface proteases causing a conformational change that promotes fusion of the viral envelope and plasma membrane. The viral genome, wrapped in a nucleocapsid, is released into the cytoplasm following the membrane fusion reaction and replication proceeds as described for HRSV.

Epidemiology

HPIV infections occur worldwide in young children with risk factors being malnutrition, vitamin deficiency, and respiratory irritants. Of the 5 million respiratory tract infections in the United States each year, HPIV is responsible for over one-third of

cases. Serologic surveys have found that by the age of 6–10 years, most children are seropositive for HPIV, demonstrating the widespread pathogenicity of this virus family. HPIV-1 to 3 are more prevalent than HPIV-4. Little is known about HPIV-4 since it is not often isolated from patients. HPIV-1 is strongly linked to croup with approximately 50% of cases being caused by the virus. Other severe symptoms include bronchiolitis, pneumonia and wheezing. HPIV-3 is second only to HRSV as a cause of pneumonia and bronchiolitis in young children.

HPIV-1 and HPIV-2 outbreaks occur in opposite years with each peaking in a year that the other wanes. The reason for this is unknown. Biennial fall outbreaks are common for both viruses with infections in children under age 5 years. Limited symptomatic infection is found in adults. HPIV-3 infections generally occur during the spring and summer months but can be found at low levels through the year. Of the HPIV viruses, HPIV-3 is most often associated with morbidity and mortality. HPIV-4 is detected at low levels throughout the year. The viruses are spread by fomites and large droplets with minimal persistence on solid surfaces.

Pathogenesis and Clinical Features

HPIV infection occurs primarily in children and is associated with upper and lower respiratory tract infections. Symptoms range from mild common cold with fever, to more severe disease such as croup, bronchiolitis and pneumonia. Classic “flu-like” symptoms are rarely seen in young children but are more common in adult infection. Croup presents with a hoarse barking cough and inspiratory stridor. This is the key clinical diagnostic phenotype for HPIV infection. Croup is the most common cause of infant hospitalization, with HPIV-1 and HPIV-2 most frequently the causative agents, although HPIV-3 has also been found. Bronchiolitis is also common in HPIV infection, especially during the first year of life. Immunocompromised children are at the greatest risk of severe HPIV infection, and in this population, it can be fatal. Minor risks of neurologic disease, apnea and bradycardia have been reported for HPIV infection. HPIV re-infection can occur throughout life with the elderly and immunocompromised at the greatest risk.

Diagnosis

Virus can be found in respiratory secretions, but the major diagnosis is from the bark-like cough and the stridor observed by chest x-ray where a “steeple sign” can be seen due to narrowing of the subglottic airway. RT-PCR is a common molecular diagnostic after infection of cell monolayers to amplify virus.

Management and Control

No treatments are licensed although acetaminophen or ibuprofen are often used for treating fever. For croup, supportive care is available including taking the child outside into cool air, having them breathe steamy air from a shower and calming them down to slow their breathing. Additionally, corticosteroids and nebulizers can be used to treat respiratory symptoms.

Rhinovirus

The Virus

Human rhinoviruses (HRV) are in the *Enterovirus* genus of the *Picornaviridae* family and cause common cold symptoms. They are the most commonly isolated respiratory virus from people with mild URTI, responsible for between a half and two-thirds of all colds. HRV is considered one of the most common human infectious agents worldwide.

Rhinoviruses have very broad genetic diversity, with over 150 different strains identified by either serology or sequencing. The phylogeny can be divided into HRV-A and HRV-B, which are the most common strains found in humans, and HRV-C, which is less common but is linked to more severe disease. HRV causes a lytic infection of the epithelial cells lining the airways with increased infection in the upper versus lower airways. This segregation is thought to be due the virus having better replication kinetics at 34°C compared to 37°C, with the nasal epithelium being at a lower temperature compared to deeper parts of the airways.

HRVs are single stranded positive sense RNA viruses with a genome size between 7 and 8 kilobases (for a schematic view of the genome organization, see Fig. 1). HRV virions are small, approximately 30 nm diameter, nonenveloped viruses (Table 1). Viral particles have an icosahedral capsid structure consisting of 60 copies each of VP-1, 2, 3 and 4. The viral particles are stable for days on surfaces and resistant to many common disinfectants.

Receptor usage by HRV depends on the subtype; minor group HRV-A bind to low-density lipoprotein receptor (LDLR) family members, the major group HRV-A and HRV-B bind to intracellular adhesion molecule 1 (ICAM-1), and HRV-C binds cadherin-related family member 3 (CDHR3). HRV is taken up from the cell surface by receptor-mediated endocytosis and a conformational change occurs in the capsid upon exposure to low pH to promote pore formation and release of genomic material into the cytosol. The RNA genome has a 5' internal ribosomal entry site (IRES) that initiates translation of the viral RNA. The genome is translated as a single polypeptide that is subsequently cleaved by host and virally encoded proteases to yield 11 viral proteins required for

replication. Newly transcribed viral RNAs can either be used for protein production or packaged into new virions for release (for a schematic view of the life cycle, see Fig. 2).

Epidemiology

HRV causes common colds around the world and humans are the only host of the virus. Adults average between 2 and 3 colds per year, with more than half of these due to HRV infection. Children typically suffer a higher frequency of colds, with estimates being up to 12 infections per year. HRV transmission is seen year-round, but cases of HRV-A and -B are seen to have two peak periods in April/May and September/October. There is an association of incidence with children returning to school. HRV-C cases appear to peak in winter months.

Virus is transmitted by droplets or fomites with close contact generally needed for cross infection between individuals. Viral particles can survive for several hours on skin which can facilitate human-to-human transmission. The virus is highly infectious, with only a small infectious dose needed to initiate disease in a human. The incubation period for infection is less than 2 days and usually requires 7–10 days for clearance.

Pathogenesis and Clinical Features

HRV infection is via the aerosol route with infection primarily occurring in the nasal or oral mucosa and eye conjunctiva. The primary site of viral replication is in airway epithelial cells. HRV infection can disrupt epithelial barrier function which can, in turn, allow translocation of pathogens across this barrier to cause disease complications. The host response to HRV is swift with an increase in systemic chemokines and cytokines that limit virus spread but causes clinical symptoms. Infection is usually mild and self-limiting, although more severe disease such as pneumonia has been seen in the elderly and immunocompromised.

HRV symptoms start with sore throat and runny nose and can develop to cough, sneezing and congestion. Other symptoms can include fatigue, body aches and loss of appetite. Patients can have several colds a year due to the wide spectrum of serotypes in the environment and the limited immune response to each strain that is produced during infection. HRV is also associated with asthma exacerbations in addition to causing common colds.

Diagnosis

HRV diagnosis is by clinical symptoms and by RT-PCR of nasal secretions. Some clinical microbiology laboratories will grow samples from nasal swabs in cell culture for analysis. The vast genetic differences between the large number of isolates makes ELISA analysis difficult due to the variability in surface antigen alleles present in the environment. Usually RT-PCR is targeted to conserved regions of the genome for diagnosis in hospitals.

Management and Control

There are no licensed therapeutics and only supportive care is given for HRV infection. Many antiviral drugs have been proposed, however, all lack potency in humans. For instance, zinc has been tried as an over the counter therapeutic but with limited success. Vaccine development is problematic due to the high variability of surface proteins, although current efforts are directed to regions of conservation between many of the serotypes. Future work on prophylaxis is ongoing.

Coronaviruses

The Viruses

Coronaviruses are part of the *Coronaviridae* family in the *Nidovirales* order that contain the largest viral RNA genomes currently known. The first two human coronaviruses (HCoV) were identified in the 1960s and are known as HCoV-229E and -OC43. These two viruses, and coronaviruses in general, were given relatively little attention until the severe acute respiratory syndrome (SARS)-CoV outbreak in 2003. Subsequently, three further HCoVs were identified. HCoV-NL63 was found in a child suffering bronchiolitis in the Netherlands, while HCoV-HKU1 was discovered in adult cases of pneumonia in Hong Kong in 2005. Finally, an outbreak of Middle East respiratory syndrome (MERS)-CoV was first identified in 2012. These six HCoVs can be broadly divided into two groups; HCoV-229E, -OC43, -NL63 and -HKU1 can be described as low pathogenicity (LP) HCoVs that typically cause mild respiratory infection. While SARS- and MERS-CoV can be considered highly pathogenic HCoVs. The unifying virology of these pathogens will be considered first, then they will be divided when discussing their epidemiology, pathogenesis, clinical features, diagnosis, management and control.

The *Coronaviridae* family can be broken into two subfamilies, the *Coronavirinae* and *Torovirinae*. The *Coronavirinae* has four groups, alpha, beta, gamma, and delta. HCoV-229E and -NL63 are alpha-coronaviruses, while the other four HCoVs are beta-coronaviruses (Table 1). The family of viruses have positive sense RNA genomes ranging from 27 to 32 kilobases (kb) (for a

schematic view of the genome organization, see Fig. 1). Coronavirus virions are spherical with an approximate diameter of 125 nm and are wrapped in a host-derived lipid envelope. The virions have large protrusions from the surface of the spike (S) protein which gives a crown-like appearance, leading to the naming of coronaviruses (corona deriving from the Latin for crown). Along with S, the viral envelope also contains matrix (M) and envelope (E) proteins. M is the most abundant protein in the virion and is thought to be responsible for the shape. The expression of M and E in a cell can produce a viral-like particle (VLP). Within the enveloped virion, the viral RNA genome is wrapped in the nucleocapsid (N) protein. All coronaviruses have these four structural proteins, but some beta-coronaviruses, including HCoV-OC43, also have a hemagglutinin esterase (HE) in the lipid envelope.

The S protein of coronaviruses is usually responsible for receptor binding and is solely responsible for membrane fusion for cellular entry. HCoVs use different cell surface receptors: HCoV-229E binds aminopeptidase N (APN), HCoV-NL63 and SARS-CoV bind angiotensin converting enzyme 2 (ACE2), HCoV-OC43 binds 9-O-acetylated sialic acids through HE, MERS-CoV binds dipeptidyl peptidase 4 (DPP4) and the HCoV-HKU1 receptor is yet to be identified. Unifying features of these receptors are that they are expressed throughout the human airway and are found on the apical surface of cells. S, a type I membrane fusion protein, requires proteolytic cleavage to activate the fusion reaction. The precise and most physiologically relevant site of membrane fusion is debated. HCoVs have been found to fuse both at the plasma membrane following cleavage by TMPRSS2, or within acidified endosomes following cleavage by cathepsins. Data appear to suggest that both routes of entry can be used, but that at least for clinical isolates of the LP-HCoVs there may be more efficient infection through cleavage by TMPRSS2, although whether fusion occurs at the plasma membrane or within endosomal compartments is unclear.

Once viral and cellular membranes fuse, the viral genome can enter the cytosol. Since the genome is positive sense, there is direct translation to produce viral proteins. ORF1a and ORF1b are translated to express the polyproteins pp1a and pp1ab. These polyproteins contain nonstructural proteins (nsp), with pp1a comprising nsp1–11 and pp1ab additionally having nsp12–16. Within these polyproteins there are two proteases, papain-like protease (PLpro) and main protease (Mpro) that release the nsps by proteolytic cleavage. Liberated nsps then regulate production of subgenomic RNAs that encode the structural and accessory genes, and controls replication of the viral genome, both of which occur through negative sense RNA intermediates.

After translation from subgenomic RNA, the structural proteins E, M and S insert to the endoplasmic reticulum membrane. Subsequently, these proteins are trafficked to the endosomal reticulum-Golgi intermediate compartment (ERGIC) where virion assembly occurs. M is the main driver of virion assembly as it is responsible for interaction with the E protein to form VLPs and interacts with N for encapsulation of the viral genome. Following the interaction of the four structural proteins and the viral genome, there is inward budding of cellular membrane to the ERGIC to produce a virion. These virions then exit the cell through the Golgi exocytic pathway and fusion of a cellular vesicle at the plasma membrane. In polarized cells, such as those in the airways, there is preferential but not exclusive, release of progeny viral particles at the apical plasma membrane (for a schematic view of the life cycle, see Fig. 2).

Low Pathogenicity Coronaviruses

Epidemiology

The four LP-HCoVs are considered to be the second most frequent causes of the common cold behind rhinoviruses. These viruses display seasonality with spread occurring in winter and spring months in temperate regions, although summer activity has also been observed. During the season, LP-HCoVs can be responsible for anywhere between 1% and 35% of acute respiratory infections. Seroprevalence levels are seen to raise through age 5 years. By adulthood, there is about 40% seroprevalence for LP-HCoVs, in the United States. Epidemiological studies of these four viruses have often found cases of co-infection with other respiratory viruses, yet the relevance of this to clinical outcome has yet to be thoroughly examined.

Pathogenesis and Clinical Features

Studying the pathogenesis of LP-HCoVs has been hindered by a lack of small animal models that support replication and/or reproduce disease. The pathogenesis of HCoV-229E has been examined in volunteers that were experimentally infected and subject to ultrastructural studies. This work demonstrated that viral infection causes epithelial cell damage, ciliary loss and cytolysis beginning at 3 days postinfection. Virus is seen to be shed for approximately 5 days, starting 48 h after initial infection, coincidentally with symptom onset. Symptoms associated with LP-HCoVs are similar to those of other respiratory pathogens; cough, sputum, rhinorrhea, tachypnea, sore throat and occasionally fever. Disease severity can be worse in the young, elderly and those with underlying health conditions, but usually infection is self-limiting and clears within a week. HCoV-NL63 has been associated with cases of croup; a study in Germany determined that up to 45% of children under 3 years of age infected with HCoV-NL63 developed croup.

Diagnosis

The most often used technique for diagnosis of LP-HCoVs is RT-PCR. It is also possible to isolate virus in cell culture, and serological assays can be used.

Management and Control

LP-HCoV infections are usually self-limiting and often not associated with severe disease. As a result, treatment of infection is usually supportive care and symptomatic relief. There are currently no direct acting antivirals against LP-HCoVs, nor any vaccines.

Highly Pathogenic Coronaviruses—SARS-CoV

Epidemiology

The SARS-CoV outbreak began in the Guangdong province of China in November 2002. However, the outbreak was not fully appreciated until early 2003 when a single infected patient traveled from China to stay at Hotel Metropole in Hong Kong. This patient, staying on the 9th floor, managed to infect over 10 people, who subsequently spread the virus throughout Asia and Canada. One of these patients traveled to Hanoi, Vietnam and was responsible for a hospital-based outbreak of 38 cases. It was from here that the highly contagious nature of this novel pathogen was reported to the WHO by Carlo Urbani, who himself became infected and died from the virus in March 2003. Within weeks of the transmission out of Hong Kong, SARS-CoV had spread to 27 countries and infected thousands of people, with about a third being healthcare workers. The virus responsible for SARS was identified in April 2003. By July 2003, the outbreak was halted through public health measures, although a handful of additional cases were detected in December 2003 to January 2004. In a little over a year, SARS-CoV infected 8098 people and was responsible for 774 deaths, with a predicted economic impact of over 30 billion USD in the Far East alone. No cases of SARS-CoV have been reported since.

SARS-CoV emerged through zoonotic transmission from the natural reservoir host, horseshoe bats. The outbreak was however facilitated by an intermediate, amplification host, of palm civets which were kept in live animal markets in China. These animals appear to be incidental hosts since serological analyses failed to detect antibodies in animals in the wild or in breeding facilities. The virus initially transmitted from animals into the human population and was found to then adapt to facilitate efficient human-human spread. Many surveillance studies have since been performed, and multiple SARS-like viruses have been found in bats, suggesting the potential for re-emergence of a similar pathogen.

Human-human transmission occurs through aerosol droplets or contaminated surfaces and fomites. It has been shown that the virus can persist for up to 2 days on environmental surfaces. Many cases were nosocomial as the majority of virus shedding only occurs after the onset of illness (around 5 days postinfection). Approximately 33%–42% of SARS cases were in healthcare works, while 22%–39% of cases were through transmission between family members. The R_0 for the virus is between 2 and 4, but measures to limit spread were highly effective and brought this down to around 0.4 to quell the outbreak.

Pathogenesis and Clinical Features

The incubation period for SARS-CoV infection is typically between 4 and 6 days. Initial presentation is general flu-like symptoms such as fever, myalgia, and lethargy, with respiratory symptoms such as cough and sore throat developing between 2 and 7 days later. The infection then progresses with more severe respiratory symptoms such as shortness of breath, pneumonia and acute respiratory distress syndrome (ARDS). Infection causes diffuse alveolar damage, lung edema, hyaline membrane and syncytium formation. Approximately half of SARS cases resulted in hypoxemia around 9 days after onset of symptoms. Many of these patients required admittance to the ICU and mechanical ventilation. A higher viral load was found to be associated with poorer clinical outcome.

Patients display widespread immune cell infiltration to the lungs. Immunopathology plays a major role in the more severe forms of SARS-CoV infection; indeed, ARDS is heavily associated with upregulation of proinflammatory cytokines and chemokines. The immunopathology of the disease is best evidenced by the fact that the most severe symptoms occur as virus titer begins to decline.

In addition to respiratory disease, SARS-CoV infection was associated with gastrointestinal symptoms such as diarrhea and vomiting. The precise cause for this is unclear and there is no evidence of fecal-oral transmission of the virus. Virus was also detected in the urine of up to 30% of patients.

The median age of SARS patients was under 45, but symptoms were typically more severe in the elderly. The case fatality for SARS-CoV infection was much higher in older patients with 43% of patients over 60 dying from infection, compared to 13% of patients under 60. About 10%–30% of patients had comorbidities associated with infection and the mortality rate in this population was 46%.

Diagnosis

Samples for diagnosis can be recovered from respiratory secretions, feces and urine. There is a higher viral load in the lower respiratory tract, so samples from that area are more reliable, but more invasive and difficult to obtain. RT-PCR, along with serological assays were used to confirm SARS-CoV infection. Virus can be isolated with Vero E6 cells, and indeed this was the approach used to determine that SARS was caused by a novel coronavirus.

Management and Control

The SARS-CoV outbreak was halted by public health intervention, not through any direct acting antiviral or vaccine. Measures such as quarantine in negative pressure rooms, handwashing, disinfection of surfaces, appropriate personal protective equipment and avoidance of contact with bodily fluid all helped to block spread of infection.

Much of the care given to SARS patients was supportive to mitigate issues of hypoxemia and ARDS. In numerous cases ribavirin along with pegylated interferon was used, although this intervention was not thoroughly tested, and retrospective studies have shown that the efficacy is debatable. Corticosteroids and thymosins were also used, but again, no thorough clinical trials were performed, and the role any of these interventions played in disease outcome remains unclear. However, convalescent patient plasma use did seem to be associated with a reduced frequency of poor outcomes when given before day 14 of infection.

To date, there are no approved direct acting antivirals against SARS-CoV. However, many compounds are currently under investigation for treating MERS-CoV infection with many of these being shown to also be effective against SARS-CoV (discussed further in the following section). Protease inhibitors did appear to have some degree of efficacy during the SARS-CoV outbreak. A number of patients received lopinavir, ritonavir or a combination of both. These drugs are licensed for use as HIV-1 protease inhibitors and are part of highly active antiretroviral therapy. Again, the use of these compounds did not undergo rigorous clinical investigation, but when used in combination with ribavirin, with or without corticosteroids, a reduction in viral load was detected and symptoms were found to subside, with disease progression being milder.

Similar to antiviral drug therapy, there is no approved vaccine against SARS-CoV infection. Multiple approaches were undertaken, however, none were successfully trialed in humans. With the emergence of MERS-CoV, there has been a renewed push for countermeasures against HCoV infection with some approaches looking to produce broadly acting vaccines. However, to date these studies are at early stages.

Highly Pathogenic Coronaviruses—MERS-CoV

Epidemiology

In June 2012, around 10 years after the emergence of SARS-CoV, a novel coronavirus was identified in the Middle East when a 60-year-old man died of acute pneumonia and renal failure in Saudi Arabia. MERS-CoV was isolated from the sputum of this patient by scientists at Erasmus Medical Center in the Netherlands and was initially called HCoV-EMC, before being re-named MERS-CoV. Retrospective studies determined that the virus had been responsible for the hospitalization of 11 patients in Jordan in April 2012. In contrast to SARS-CoV, there has been no explosive spread of MERS-CoV. The largest outbreak occurred in Spring 2014 which saw around 500 hospital acquired cases in Saudi Arabia. May 2015 also saw a large outbreak in South Korea initiated by a patient that had traveled to the Middle East. This outbreak saw 186 infections across 16 hospitals with 36 deaths. The epidemic was halted largely through quarantine measures, with around 17,000 people being isolated.

While MERS-CoV has reached 27 different countries, the vast majority of cases are confined to the Middle East. Again, in contrast to SARS-CoV, MERS-CoV continues to sporadically cause disease and in early 2018 there have been over 2100 cases, responsible for around 750 deaths. MERS-CoV therefore has a significantly higher case fatality ratio than SARS-CoV and has caused fewer cases over a longer period of time.

Similar to SARS-CoV, MERS-CoV has close ancestors in bats. MERS-CoV is also found extensively in dromedary camels in the Middle East, Northern and Eastern Africa. It is estimated that in certain areas, the seroprevalence of MERS-CoV antibodies in dromedary camels may be as high as 90%. The ubiquity of MERS-CoV in camels is most likely responsible for the continued, sporadic, emergence of cases due to close contact between humans and camels, particularly in the Middle East. It is worth noting that MERS-CoV is found extensively in camels in regions of Africa, yet there have been very few reported cases of human infection on this continent. There may be various reasons for this such as reduced surveillance, differences in the interaction between humans and camels, or the spread of a virus with less virulence. In addition to camels, MERS-CoV has been found in sheep, goats, cows, water buffalo and alpaca, suggesting the virus could become more widespread.

MERS-CoV does not seem to have adapted to spread from human-to-human effectively, unlike SARS-CoV. The majority of MERS-CoV cases are through zoonotic events. Most human-to-human transmission of MERS-CoV has been nosocomial, with estimates suggesting between 62% and 79% of cases in a hospital setting, compared to 12%–21% between family members. This nosocomial transmission likely relates to the fact that there is only significant virus shedding following the onset of symptoms. Poor human-to-human transmission of the virus is reflected in the fact the R_0 value is currently estimated to be around 0.7.

Of all MERS cases to date, around 66% have been in males. However, there does not seem to be any sex-based differences in the case fatality ratio. A likely explanation may be cultural and as a result of the relative levels of interaction with the animal reservoirs of the virus. The median age of MERS patients is about 50 years, older than seen for SARS cases. Age appears to be associated with an increased risk of infection. The clearest risk factors are underlying comorbidities. Diabetes is the leading comorbidity, seen in 68% of cases, but chronic renal disease (49%), obesity (34%), chorionic cardiac disease (28%) and other lung diseases are also highly associated. Approximately 75% of MERS patients have underlying conditions, and the case fatality ratio in this population is close to 60%.

Pathogenesis and Clinical Features

MERS-CoV infection causes a spectrum of disease, from mild respiratory symptoms, usually confined to the upper respiratory tract, to more severe disease impacting the lower airways. The virus infects cells throughout the lungs via the receptor DPP4, which is found on type I and II pneumocytes, nonciliated bronchial epithelial cells, endothelial cells and some hematopoietic cells. The receptor is found at lower abundance in the upper respiratory tract, leading to higher viral load in the lower airways. DPP4 is also found in the kidneys, intestine, liver, thymus and bone marrow.

The incubation period for the virus is 2–14 days with the median being 5–7 days. For patients that suffer severe disease, there is usually a 4-day period of symptoms before hospitalization. MERS initially starts with flu-like symptoms, but then rapidly progresses to pneumonia and ARDS in severe cases (a more rapid progression than seen in SARS patients). Similar to SARS-CoV infection, there can also be gastrointestinal involvement with diarrhea, abdominal pain and vomiting often seen.

The full extent of the pathogenesis of MERS-CoV infection is still being established, and at the time of writing, only two postmortem examinations have been performed. The first of these was a full autopsy of a 45-year-old male who died in Abu Dhabi in April 2014. Prior to hospitalization, this patient had a 4-day history of fever, rhinorrhea and productive cough and was diagnosed with bronchitis. He developed a persistent cough and shortness of breath and was diagnosed with pneumonia before being admitted to the ICU. His condition worsened, he developed kidney injury and renal failure and died 3 days later. An autopsy was performed 10 days postmortem. The patient had clear signs of pleural effusion, pericardial effusion, abdominal effusion, edematous and consolidated lungs and generalized congestion. Additionally, there was diffuse alveolar damage, denuding of bronchiolar epithelium, hyaline membrane formation, alveolar fibrin deposits, type II pneumocyte hyperplasia, syncytia formation and immune cell infiltration to the lungs. Extensive damage to the kidney was also seen, but there was no evidence of virus dissemination to extra-pulmonary sites suggesting other mechanisms for this damage. The lung pathology seen in this patient was similar to that seen in SARS patients.

The second postmortem examination was of a 33-year-old male who died in Riyadh in September 2015. This patient was additionally suffering from T-cell lymphoma, which had previously been treated with chemotherapy and radiotherapy. He had been admitted to hospital in Riyadh in May 2015 for further chemotherapy and possible stem cell transplantation. The patient initially presented with cellulitis and sepsis in July. His condition worsened as he developed thrombocytopenia and neutropenia along with a fever and productive cough with chest infiltrates revealed by X-ray. At this stage the patient's sputum suggested bacterial pneumonia and was negative for MERS-CoV. But 20 days later, the patient tested positive for MERS-CoV and with increasing hypoxemia was admitted to the ICU and given mechanical ventilation. The patient died 4 days later from refractory shock and hypoxemia. Tissue samples were collected within 45 min of death, but no full autopsy was performed. Samples demonstrated severe acute hemorrhagic pneumonia, diffuse alveolar damage and immune infiltrates, and many other similarities to the previously described autopsy. Electron microscopy examination revealed the presence of virus particles in pneumocytes, alveolar macrophages, renal tubular epithelial cells and macrophages infiltrating skeletal muscles. In contrast to the previous case, there was evidence of systemic spread of MERS-CoV. However, this patient may be an atypical example of infection owing to potential exacerbation of symptoms as a result of the immunosuppression from lymphoma and chemotherapy.

Currently, a full understanding of the pathogenesis of MERS is limited by the lack of human postmortem examination and the ongoing development of appropriate animal models.

Diagnosis

The WHO have developed guidelines for the diagnosis of MERS-CoV infection. These state that sampling should be from the lower respiratory tract during the acute phase of illness and use RT-PCR to detect the presence of two parts of the MERS-CoV genome; a region upstream of the E gene (UpE) and in the ORF1ab gene. Serological tests can also be used to test for MERS-CoV infection with ELISA, immunofluorescence, and microneutralization assays all employed.

Management and Control

Currently, the best forms of control for MERS-CoV infection are public health interventions. Quarantine methods, appropriate personal protective equipment, avoiding contact with bodily fluids, and general hygiene measures can all reduce spread of infection. Moreover, limiting exposure to the animal reservoir may aid in reducing infection.

There is currently no approved vaccine against MERS-CoV, although much research is ongoing. Inactivated, live-attenuated, vector, subunit, DNA and recombinant vaccine strategies are all being explored. Along with vaccine approaches in humans, camel vaccinations are being developed to look to reduce zoonotic transmission of the virus.

Along with vaccination approaches, immunotherapy measures are being explored. Passive immunotherapy with convalescent patient plasma has been tested, although there is currently a lack of surviving patients with high antibody titers to test this approach effectively. Neutralizing antibodies targeting the spike protein of MERS-CoV are also being examined but have yet to be fully trialed in humans. Along with antibodies targeting the spike protein of the virus, monoclonal antibodies targeting the DPP4 receptor are also being examined.

There are also no approved direct acting antivirals. However, many avenues are being explored to inhibit various aspects of MERS-CoV infection. Lopinavir and ritonavir have been used in MERS patients alongside interferon and ribavirin, however, as in

SARS patients, the efficacy remains unclear. Other protease inhibitors that were initially examined as anti-SARS-CoV compounds are being explored but have yet to be fully evaluated in vivo. Repurposing of currently approved drugs is a common theme among the currently examined antiviral compounds. Antimalarials such as chloroquine, amodiaquine, or mefloquine have all been found to have antiviral activity against SARS- and MERS-CoV. A widely used antidiarrheal agent, loperamide, was found to be inhibitory to coronavirus replication through in vitro screening. Cyclophilin inhibitors currently used as immunosuppressive agents can inhibit replication as can various kinase inhibitors in use for cancer treatment. However, most of these compounds have only been tested in vitro or have limited in vivo examination. Nucleoside analogs are being explored to inhibit the RNA-dependent RNA-polymerase such as GS-57434 and BCX4430.

Overall, the best approach for control of MERS-CoV is public health measures to limit infection. There are no approved therapies or vaccines, but extensive research is taking place to move toward such approaches. Much of this work is also looking for broad-activity of any compound to not only protect against MERS-CoV infection, but also any novel coronavirus that may emerge in the future.

Adenoviruses

The Viruses

Adenoviruses are a large family of double strand DNA viruses. There are seven different species, A–G, with over 50 distinct serotypes. The viruses are in the *Mastadenovirus* genus, family *Adenoviridae*. The first identification of an adenovirus came in 1953 when a transmissible agent was found in adenoid tissue, giving rise to the name.

Adenovirus virions are nonenveloped, have icosahedral symmetry and are around 90 nm in size. The viral capsid is made up for 252 capsomere proteins that are divided into three types, hexons (240 copies), penton bases and penton fibers (12 base/fiber copies) (Table 1). Each vertex of the icosahedral virus has a penton base/fiber protruding from it. These three proteins are all exposed to the immune system and are the targets for neutralizing antibodies. The genome inside the virion is linear, nonsegmented double stranded DNA of between 26 and 46 kilobase pairs (for a schematic view of the genome organization, see Fig. 1).

Virus entry to cells and uncoating to release the genome is a complex, multistep process. Initially, the virus binds to a cellular receptor through the penton fiber. Two receptors are used depending on the viral species, with most human adenoviruses (HAdV) using the coxsackie B and adenovirus receptor (CAR). HAdV species B utilizes CD46 instead. Certain strains of HAdV have also been suggested to use desmoglein-2, sialic acids or GD1a glycan as receptor molecules.

Following initial interaction with surface receptors, the virus binds to a second receptor in the integrin family of proteins, in particular αV integrin, through the penton base. Binding to the two receptors begins the uncoating process. Interaction between penton fibers and CAR triggers drift of the virus along the plasma membrane in an actomyosin-2 dependent fashion. This drift exerts a pulling force on the virus which, if also attached to relatively immobile integrins will start to exert pressure on the virion. As such, penton fibers begin to shed from the virus at the cell surface.

Along with promoting the initial stages of virus disassembly, interaction with integrins triggers an endocytic response of the cell, causing uptake of virions either in a clathrin-dependent or macropinocytic manner. In the endosomal system, further rearrangement of the capsid occurs to allow release of protein VI. HAdV protein VI is responsible for rupturing endosomes to allow for release of the partially disassembled virion into the cytosol.

Once in the cytosol, HAdV associates with the microtubule network through the dynein motor protein and is trafficked to the nucleus. The remaining capsid proteins then interact with the nuclear pore complex and the joint interaction between microtubule motors, nuclear porins and viral capsid proteins leads to the final stages of uncoating to deposit the double stranded DNA genome into the nucleus.

The HAdV genome is treated similarly to cellular DNA and transcribed to give mRNAs that are translated to produce the viral proteins. Transcription/translation occurs in early and late phases. Early gene expression produces proteins that are nonstructural and promote viral replication. For instance, E1A and E1B which bind to Rb and p53, respectively, promote progression to the cell cycle to allow co-option of cellular DNA replication machinery for replication of the viral DNA. These early genes also play roles in expression of the late genes such as the virally encoded DNA polymerase. In the late phase, structural proteins are produced to assemble new virions. Assembly occurs in the nucleus where the viral DNA is encased in new capsid. Progeny virions are released through cell lysis (for a schematic view of the life cycle, see Fig. 2). However, it is also possible for HAdV to enter into a latent life cycle; this life cycle was how adenovirus was first discovered in adenoid tissue.

Epidemiology

HAdVs cause a spectrum of disease depending on the species but respiratory infections are among the most common, especially in children under 5 years. It is estimated that globally, about 5%–7% of pediatric respiratory tract infection are from HAdV. Most of these infections are mild and self-limiting causing general common cold symptoms. However, there can be more severe disease such as pneumonia, bronchitis and croup. Along with respiratory infection, HAdV infection can cause conjunctivitis, gastroenteritis, hepatitis and myocarditis.

Of the various species of adenovirus, B, C and E have been found to infect the respiratory tract. Infections by respiratory HAdVs occurs globally and do not appear to show seasonality. When outbreaks do occur, they are often in small populations such as in

hospitals and particularly in military installations. Most infections occur in young children or immunocompromised adults, but there have been severe outbreaks in healthy adults. The reasons for the spectrum of disease severity are not fully clear, but it is hypothesized that it may be down to emergence of novel strains of HAdV. For instance, 2007 saw the emergence of a novel HAdV-14 that initially spread in US military personnel and then in civilian populations that caused pneumonia and ARDS. Antibody responses to HAdV infections have been shown to be effective and long lived, suggesting that the emergence of strains that can avoid preexisting immunity may indeed play a role in more severe infections.

Respiratory HAdVs are transmitted in aerosol form through coughs and sneezes and through contaminated surfaces. Adenoviruses have a high degree of environmental stability, they are unperturbed across a pH range of 5–9 and are resistant to isopropyl alcohol, ether, and chloroform. HAdV can survive on surfaces for weeks at room temperature and even longer at colder temperature.

Pathogenesis and Clinical Features

Respiratory tract infection by HAdV typically causes mild, self-limiting, common cold symptoms. The most common manifestations of HAdV infection are cough, chest pain, headache, malaise, pharyngeal symptoms and fever. The virus has a lytic life cycle, so causes damage to the respiratory tract through cell death and can cause infiltration of immune cells. More severe forms of disease can occur, particularly in the young or immunocompromised that are associated with pneumonia or bronchitis. Children under the age of 5 years can often develop fever, pharyngitis and otitis media, which can occur in up to 30% of cases.

Patients are seen to develop a neutralizing antibody and T-cell immune response to HAdV infection that protects in a type-specific manner. However, because of the various species of HAdV, re-infection is common. Owing to the immune response many re-infections can be asymptomatic, and indeed, up to 50% of HAdV infections are thought to be asymptomatic due to the combination of latency and the immune response.

Diagnosis

Virus can be found in respiratory, ocular and ear secretions, but there is a need for clinical correlation when virus is detected because asymptomatic shedding is common. Virus can be grown out of samples using various cell lines such as HEp-2, HeLa and A549 and can be easily detected through the cytopathic effect infection causes. PCR is the most sensitive method for detection, but again requires clinical correlation due to asymptomatic HAdV infection. Point of care immunochromatography tests are also available.

Management and Control

Owing to the usually mild and self-limiting nature of HAdV infection, there is little impetus for intervention. No treatments are currently licensed, although cidofovir has been suggested to have therapeutic potential in pediatric patients. A live-attenuated oral vaccine is licensed for use in US military recruits attending basic training, but this is not available to the public. General countermeasures of hygiene and surface disinfection with virucidal agents are routinely used to limit spread.

Human Bocavirus

The Virus

Human bocavirus (HBoV) was first identified in 2005 by screening of nasopharyngeal aspirates for novel viruses causing respiratory disease. A random PCR amplification strategy followed by sequencing and bioinformatics identified a previously unknown member of the *Parvoviridae* that became known as human bocavirus. The name derives from there being genetic similarities to two already defined parvoviruses, bovine parvovirus 1 and canine minute virus. Since the initial identification, three further subtypes of HBoV have been found in stool samples (HBoV2, 3 and 4).

HBoV is a member of the *Parvoviridae* which are small single stranded DNA viruses. Parvoviruses are among the smallest known viruses both in terms of genome, around 5–5.5 kilobases, and particle size, ranging from 18 to 26 nm (Table 1). Virions are nonenveloped and made up of 60 capsid proteins. The HBoV genome contains three ORFs (ORF1–3). There are four nonstructural proteins encoded from ORF1, NS1–4, and an additional nonstructural protein, NP1 encoded from ORF2. The final ORF encodes the three capsid proteins, VP1–3.

The precise infectious life cycle of HBoV has yet to be fully characterized. It has been suggested that sialic acids act as the receptor at the cell surface, however, the virus has proven hard to grow in many cell lines which could suggest other receptor requirements. Uptake from the cell surface is thought to be through a clathrin-mediated endocytosis. HBoV escape from the endosomal system is dependent on a phospholipase A2 domain in the VP1 protein, although the precise mechanism of escape is unclear. Replication occurs in the nucleus, and similar to other parvoviruses, HBoV requires many cellular DNA replication components. The virus can be released from cells through a lytic process, but can also be persistent in an episomal form, the determinants of these life cycles is unclear.

Epidemiology

HBoV has been found to have a worldwide distribution, with infection occurring year-round, although there does appear to be more cases in winter and spring months. A large meta-analysis of epidemiological studies conducted between 2005 and 2016 suggested that HBoV is found in about 6% of respiratory infection cases. This study also showed that HBoV is often detected in conjunction with other respiratory viruses, with over 50% of cases being co-infection. This high degree of co-infection has caused some suggestion that HBoV may not cause disease itself and just be present in a certain percentage of the human population. However, HBoV has been detected in cases of acute respiratory infection where no other causative agents could be found.

The greatest disease burden for HBoV appears to be in children between 6 and 24 months of age. Studies suggest that HBoV can be found in up to 20% of children suffering acute respiratory infection. The virus has also been associated with community acquired pneumonia in young children.

There are some limitations to the current knowledge of HBoV epidemiology. Virus has been found to shed for up to 12 months after acute infection. Thus, detection may not necessarily indicate a causative link to disease. Moreover, it has been suggested that the routine use of DNA and PCR to detect HBoV may not be appropriate due to prolonged shedding and persistence. An alternative approach of using RT-PCR to look for a spliced form of the capsid mRNA that is only present during active replication. Using this approach, HBoV was still associated with community acquired pneumonia in young children, but at much lower levels than when using DNA; approximately 10% of cases were suggested to be HBoV positive by DNA, compared to 2% by mRNA.

Pathogenesis and Clinical Features

The pathogenesis of HBoV infection is not well understood owing to the lack of an animal model and difficulties of in vitro study, although new culture systems are being developed. The understanding of HBoV pathogenesis is also clouded by the fact that the virus has a high prevalence of detection in patients infected with other viruses known to cause respiratory infection.

Studies in human airway epithelial cell culture models have suggested that HBoV infection is highly disruptive. HBoV was found to perturb tight-junction barriers, cause a thinning of epithelium, a loss of cilia and epithelial cell hypertrophy. HBoV has also been found to cause cell death, with both apoptotic and pyroptotic mechanisms suggested. It could therefore be speculated that HBoV infection in humans may disrupt the respiratory tract epithelia and cause an inflammatory response which could contribute to pathogenesis.

Symptoms associated with HBoV range from mild common cold to more severe disease. The most commonly reported symptoms in clinical studies are cough, fever, rhinorrhea, asthma exacerbation, bronchiolitis, acute wheezing and pneumonia. Viremia has also been observed in patients and viral genetic material has been detected in urine and stool. HBoV has been suggested to be associated with gastrointestinal symptoms such as nausea, vomiting and diarrhea.

Diagnosis

HBoV is most commonly detected by PCR. Virus can be detected either from respiratory secretions or stool samples. Patients have also tested positive for HBoV specific antibodies and ELISA tests can be performed.

Management and Control

The study of HBoV is largely in its infancy and there is still some debate about whether the virus is an etiologic agent of acute respiratory infection. As such, there are no antivirals or vaccine candidates against the virus.

Additional Viruses With Respiratory Transmission

Measles Virus

Measles virus (MV) is in the *Morbillivirus* genus, family *Paramyxoviridae*. Similar to the other Paramyxoviruses discussed in this article, measles has a nonsegmented, negative sense, single stranded RNA genome, which is roughly 16 kilobases in length. This genome encodes six structural proteins: nucleoprotein (N), phosphoprotein (P), matrix (M), fusion (F), hemagglutinin (H) and large (L). In addition, there are two nonstructural proteins, V and C, which are encoded within the P gene. MV particles are spherical and roughly 150–300 nm in diameter. Virions are enveloped and have the F and H proteins protruding on the surface that regulate cell entry. Inside the virion, the RNA genome is bound by the N protein which associates with the RNA-dependent RNA-polymerase L, and the cofactor P, as a ribonuclear protein complex. This complex is surrounded by the M protein.

Cell entry of MV is regulated by the H and F proteins. H is responsible for receptor binding. Wild type MV bind to CD150/SLAMF7 that is found on the surface of B and T lymphocytes, immature thymocytes, monocytes and dendritic cells. In contrast, the attenuated form of MV used for vaccination uses CD46 that is found ubiquitously on nucleated cells. MV can also utilize nectin-4. Following receptor engagement, fusion of the viral envelope and cellular membranes is mediated by the F proteins and occurs at neutral pH. The genome is then replicated in a similar fashion to that described previously for other paramyxoviruses.

MV is a highly contagious pathogen, with an R_0 value of between 12 and 18. Indeed, it is estimated that in an immunologically naïve population, 90% of people in close contact with an infected individual will contract the virus. MV has been shown to spread by respiratory droplets and aerosolized particles, but infects immune cells resident in the lungs, rather than respiratory epithelial cells, as a result of the tropism imposed by CD150/SLAMF usage. Symptoms typically develop 9–12 days following exposure. Initial symptoms present with a fever, cough, conjunctivitis and coryza. Over time, further, highly characteristic, systemic symptoms appear such as Koplik's spots in the mouth and an erythematous, maculopapular rash. Further complications can occur such as diarrhea, blindness, encephalitis and pneumonia. After spreading through the blood stream in lymphocytic cells, MV returns to, and infects, airway epithelial cells from the basolateral side through nectin-4, allowing for respiratory shedding and onward transmission.

A highly effective, live-attenuated vaccine is available. The vaccine was originally developed by John Enders in 1963 and is now routinely given to children before the age of 18 months, along with vaccines against mumps and rubella (MMR). Immunity to measles virus is lifelong and the virus is on a target list for eradication by the WHO.

Enterovirus-D68

Enterovirus-D68 (EV-D68) was first identified in California in 1962 from children suffering severe respiratory tract infections and pneumonia. The virus is in the *Picornaviridae* family. Like other picornaviruses, EV-68 virions are small at around 18–30 nm, made up of four structural proteins and are nonenveloped. The genome is approximately 7.5 kilobases and produces 11 proteins that are released from a single polypeptide.

EV-D68 appears to require sialic acid for infection, and in vitro studies have suggested that sialic acid binding causes virus uncoating. ICAM-5/telencephalin has also been suggested as a receptor. Once inside cells, EV-D68 replicates similarly to other positive sense RNA viruses, and particularly the already discussed rhinovirus, another member of the *Picornaviridae*.

From initial identification in 1962, until the early 2000s, EV-D68 infection was considered rare. However, in recent years there have been large scale outbreaks of the virus, especially in the United States which has seen epidemics in 2014 and 2017. Infection is typically associated with respiratory symptoms, either mild common cold, or more severe pneumonia. For a period, EV-D68 was referred to as rhinovirus 87 by some. In contrast to many other enteroviruses, EV-D68 is sensitive to low pH and therefore does not effectively infect through the gastrointestinal tract, leaving the respiratory tract as the primary site of infection. Similar to rhinovirus, EV-D68 has been found to replicate better at lower temperatures. In addition to respiratory symptoms, EV-D68 has been associated with cases of acute flaccid myelitis, similarly to poliovirus, suggesting the virus may be capable of infection at sites other than the lungs.

To date, there is no effective antiviral therapy or vaccine against EV-D68 and care is supportive and symptomatic.

Enterovirus 71

Enterovirus 71 (EV71) is another *Picornavirus*. EV71 was also identified in California, a number of years after EV-D68 in 1969. EV71 utilizes P-selectin glycoprotein ligand-1 and scavenger receptor class B member 2 as receptors for infection. EV71 is best known for causing hand-foot-mouth disease, largely in the Asia-Pacific region, and in some cases severe neurological symptoms. However, the virus is also associated with respiratory disease such as pharyngitis, bronchiolitis, croup and pneumonia, mostly in young children. As with most other viruses discussed in this article, there is currently no treatment or antiviral therapy for EV71, but research is ongoing in the area.

Conclusion

Respiratory viruses are the most frequent causes of human disease worldwide. Each year, this broad group of pathogens is responsible for a huge number of deaths and economic loss through days of sickness. Moreover, owing to the nature of respiratory transmission, this category of viruses has the potential for wide-ranging spread. SARS-CoV, a virus that reached 27 countries within a matter of weeks, highlights the explosive outbreak potential of respiratory pathogens. Emergence of novel respiratory viruses carries with it the fear of pandemic disease spread. To date there is generally a lack of antiviral therapy or vaccination against any of these viruses, further fueling fears for far reaching spread. By developing a deeper understanding of how these viruses replicate, cause disease and transmit, we will be able to be prepared for, and counter, the next great pandemic respiratory virus.

Introduction

Restriction-modification (R-M) systems are exclusive to unicellular organisms and are ubiquitous among bacteria. They are one of the primary defense mechanisms against bacteriophage infection and other invading DNA elements. That the R-M systems constitute prokaryotic arsenals against invading genomes was appreciated by the discoveries of Arber and co-workers as early as 1962. Typical R-M systems comprise two distinct enzymatic activities: (i) a restriction endonuclease (REase) activity that cleaves phosphodiester bonds of the DNA backbone and (ii) a methyltransferase (MTase) activity that catalyzes the addition of a methyl group from the donor S-adenosyl methionine (Adomet) to DNA adenine or cytosine. In every R-M system, both enzyme activities recognize the same specific nucleotide sequence (termed the recognition site). Methylation of host genome recognition sites prevents restriction and thus provides the R-M system with an intrinsic basis for distinguishing self from non-self; each system is hardwired for surveillance of a particular recognition sequence. With the ability of the gene pair to target the incoming DNA for cleavage and protect self-DNA from being degraded, R-Ms can be considered as primitive immune systems. With the rapid strides made in our understanding of Clustered Regularly Interspaced Short Palindromic Repeat (CRISPR)-Cas interference, they appear to fit in as bacterial adaptive immune systems in accordance with their mode of functioning. The functionally diverse R-M enzymes also provide excellent model systems to study protein-nucleic acid interactions and to engineer new specificities.

When the phenomenon of R-M was discovered more than six decades ago, little did the researchers imagine their wide-spread occurrence, diversity in their structure, function, and mechanisms, or their utility as molecular scissors for genetic engineering. It is evident that R-M systems represent one of the largest groups of enzymes, some having very high turnover while others catalyze only one round of reaction. Diversity is seen in their subunit composition, metal ion requirement for binding and/or cleavage, cleavage characteristics, mode of DNA binding, and catalytic mechanism. The accumulation of a large body of literature on these various aspects on R-M points to how the field has evolved over the years.

R-M Systems as Engines of Diversity

R-M systems are broadly classified as Type I, Type II, Type III, and Type IV based on their subunit structure, oligomeric status, recognition sequence, cleavage characteristics, cofactor requirements, mode of action, and use of a modified or unmodified substrate (Table 1). The REase can be a very simple endonuclease, as in the case of Type II systems, or a more complex, multi-subunit molecular machine, exemplified by Type I and Type III enzymes. Type I R-M systems are comprised of subunits that exhibit three functions: host specificity determinants (Hsd) - restriction (HsdR), modification (HsdM), and specificity (HsdS). The Type I systems form two configurations of these three subunits: (i) a holoenzyme with heteropentamer organization (HsdR₂M₂S) or its dimer that exerts both

Table 1 Properties and cleavage characteristics of four types of restriction modification systems (REBASE: <http://rebase.neb.com/rebase/rebase.html>)

Type	Examples	Subunits		Recognition/cleavage	Co-factor(s)	No. of REases – cloned (putative) ^a
I	EcoKI EcoBI	R ₂ M ₂ S/ M ₂ S	Multifunctional protein with restriction, modification and specificity subunits	Asymmetric and bipartite recognition site. Cleavage remote (1000–10,000 bp) from recognition site	Mg ²⁺ , ATP, Adomet	115 (19,191)
II	EcoRI	R ₂ and M	Separate restriction and modification.	Cleavage within or near the recognition sequence	Divalent metal ion	4260 (29,209)
III	EcoRV EcoP1 EcoP15	R _{1–2} M ₂	Many subtypes (see Table 2) Heterodimer with M and R subunits	Cleavage at a short distance (~25bp) from recognition site. Two non- palindromic sites in opposite direction	Mg ²⁺ , ATP, Adomet	22 (7509)
IV	McrBC McrA	R	One or two subunits	Target methylated/modified DNA	Mg ²⁺	19 (11,681)

R – Restriction, M – Methylation, S – Specificity subunit, Adomet – S-Adenosyl methionine, REase – Restriction endonuclease.

Table 2 Subtypes of Type II REases (REBASE: <http://rebase.neb.com/rebase/rebase.html>)

Subtype ^a	Defining feature	Example		No. of REases ^c (including putative)
		REase	Recognition sequence ^b	
A	Recognizes asymmetric sequence	BbvCI	CCTCAGC (–5/–2)	–
B	Cleaves both sides of recognition site	Bcgl	(10/12)CGAN ₆ TGC(12/10)	28
C	Combined R and M in one polypeptide	Gsul	CTGGAG(16/14)	–
E	Two targets (one effector, one cleaved)	EcoRII	/CCWGG	12
F	Coordinated cleavage of two sites	SgrAI	CR/CCGGYG	8
G	Cleavage effected by Adomet	BseRI	GAGGAG(10/8)	12,162
H	Similar to Type I gene structure	Bcgl	(10/12)CGAN ₆ TGC(12/10)	3
M	Methylated target	DpnI	GA/TC	796
P	Palindromic recognition site and cleavage	KpnI	GGATC/C	13,872
S	Asymmetric recognition and cleavage	FoKI	GGATG (9/13)	3070
T	Heterodimeric R proteins	BsII	CCN ₅ /N ₂	–

^aSubtypes are not mutually exclusive. For example FokI is of subtype A and S.

^bCleavage position is marked by/and number denotes bases after recognition site on top and bottom strand respectively.

Adomet – S-Adenosyl methionine, REase – Restriction endonuclease, – denotes they are included in other subtypes.

the REase and MTase activities, and (ii) a HsdM₂S alone that has methylation activity. Sequence specificity in Type I systems is achieved by HsdS, which contains two target recognition domains that recognizes sequences on both DNA strands. These enzymes recognize asymmetric bipartite sequences comprising a 6- to 8-bp nonspecific spacer sequence flanked by 5' trinucleotide- and 3' tetra- or pentanucleotide-specific sequences. Type I enzymes cleave DNA 1000–7000 bp away from the recognition sequence in a reaction requiring ATP, Mg²⁺ and Adomet. Various models for the mode of cleavage have been proposed- (a) enzyme tracking along the DNA, forming ever larger loops until the cleavage site is reached (b) the requirement of at least two recognition sites wherein two enzyme molecules bind and the translocating enzymes are drawn together, to collide and trigger DNA cleavage.

Type II R-M systems consist of two separate polypeptides (REase and MTase) that act independently of each other. Generally, Type II REases are homodimeric or homotetrameric; they cleave DNA at or near their recognition site. Due to their enormous diversity, Type II systems are further classified (Table 2) into 11 non-mutually exclusive subgroups. The four abundant subtypes include Type IIP (recognize and cleave palindrome sequences), Type IIS (recognize asymmetric recognition sequences and cleave away from the recognition site), Type IIG (Adomet effects cleavage activity) and Type IIM (cleaves methylated recognition sequences). Among them, Type IIP enzymes are the best studied, as they are the primary tools for genetic engineering.

Type III R-M systems are encoded by two genes, *mod* and *res*. The R-M enzyme is composed of two subunits of MTase (Mod) and a REase subunit (Res) having an ATPase and an endonuclease domain. Type III REases cut DNA 25–27 bp away from the recognition site and show a strong preference for cleavage where there are two copies of their asymmetric un-methylated recognition sites in an indirectly repeated, head to head orientation within a distance up to 3.5 kb. DNA cleavage occurs at one of the two asymmetric sites, 25 or 26 nt downstream in the top strand and 27 or 28 nt downstream from the recognition site in the bottom strand. Interestingly, after cleavage, the enzyme remains bound to the still intact recognition site. The dimeric Mod (M₂) or the trimeric Res-Mod (RM₂) complex catalyzes hemi-methylation of the DNA at 4–6 bp asymmetric recognition sites. Type III restriction enzymes must communicate between a pair of distant sites in order to cleave a DNA substrate. A variety of biophysical, biochemical and single-molecule studies were carried out over the last decade on the Type III RM enzymes, EcoP1I and EcoP15I. The basis of long-distance communication for which a low-level ATP hydrolysis is required has not been adequately defined. Several models for DNA cleavage have been proposed, driven by either active DNA translocation, passive three-dimensional diffusion or both DNA looping and limited translocation.

Type IV systems recognize modified DNA with low sequence selectivity; they exhibit separation of DNA binding and cleavage into different domains on the same protein, or even into different polypeptide chains. Finding genes encoding RglA and RglB (restriction of glucoseless phage) that restrict non-glucosylated hydroxymethylcytosine in T-even phages led to the discovery of a new class of R-M system. The *rgl* genes were renamed *mcrA* and *mcrBC* (modified cytosine restriction) and were classified as Type IV modification-dependent REases. *Escherichia coli* K12 strains code for at least three REases selectively directed against DNA containing modified bases. These enzymes are encoded by *mcrA*, *mcrBC*, and *mrr*. REases that cleave DNA containing modifications such as m⁵C, hm⁵C, ghm⁵C, m⁶A, m⁴C and more recently phosphorothioate DNA are loosely grouped as Type IV REases.

While the REases exhibit a wide diversity with respect to a number of characteristics, MTases are primarily of three types: two involve catalyzing methyl group transfer to the amino groups of adenine (N⁶-methyladenine – m⁶A) and cytosine (N⁴-methylcytosine – m⁴C), and a third type catalyzes methyl group transfer to the cytosine pyrimidine ring (5-methylcytosine – m⁵C). While all three types of methylation have been reported to be catalyzed by Type II R-M systems, so far only m⁶A catalysis have been observed in Type I and Type III R-Ms. Recent advances in the application of single-molecule real-time DNA sequencing to analyse DNA methylation have revealed for the first time comprehensive pictures of the genome-wide distribution of methylation sites (methylome) in various bacteria.

R-M systems often spread by horizontal gene transfer between microbes. In such a scenario, to facilitate timely expression of MTase before REase, regulatory elements of the R-M systems control REase expression in an intricate fashion through gene organization, *cis*-acting elements and *trans*-acting factors. Typically, the *trans*-acting transcription factor C protein acts as repressor that is transcribed prior to REase gene expression, whereas the MTase is transcribed from a separate promoter. The two promoters of the R-M system are found arranged in either a convergent or in a divergent fashion. This arrangement ensures that the REase gene is repressed and the C protein is auto-regulated.

Sequence analysis of a large number of bacterial and archaeal genomes has identified R-M systems in a majority. More than 90% of the sequenced genomes possess at least one R-M system with a direct correlation of their occurrence to the size of the genome. R-M systems are evenly distributed in bacteria and archaeal genomes; so far 15,601 REases are found in 3623 bacterial genomes and 495 REase genes in 153 archaeal genomes. R-M systems of archaea usually function at higher temperatures. *Helicobacter pylori*, *Neisseria species*, and *Campylobacter species* are exceptions in that they have an unusually large numbers of R-M systems relative to their genome size. This feature may reflect the evolution of additional cellular functions (see below). Analysis of the genome sequences of more than 75 *H. pylori* strains identified an extraordinary number of genes (~45) having homology to R-M genes in other bacterial species. In addition all *H. pylori* strains possess their own unique complement of active R-M systems. Some strains even encode members of all four types of R-M systems. An overview about known and predicted R-M genes for many *H. pylori* strains can be found in the REBASE database (see “Relevant Website section”).

Structure, Mechanism, and Organizational Diversity of R-M Systems

Although Type I enzymes were discovered first and now all four kinds are abundant in microbes, the number of Type II enzymes exceeds all others (Table 1). While Type II enzymes are by far the simplest, they are highly diverse with respect to their cleavage characteristics, reaction mechanism, active sites and several other features. Since the enzymes serve as tools for recombinant DNA technology, they are well studied, including structure determination and engineering new specificities. So far, five types of catalytic folds have been found: PD-(D/E)XK, PLD, HNH, GIY-YIG, and HALF-PIPE (Table 3). Many structurally characterized REases belong to the PD-(D/E)xK superfamily, which is, the most common and well-studied group of REases. The HNH superfamily of REases is the second largest group of enzymes; it is characterized by the presence of a $\beta\beta\alpha$ -me finger fold. PD-(D/E)xK, HNH, and GIY-YIG catalytic motifs are widespread among DNA transaction enzymes, including mobile intron-encoded homing endonucleases and sequence non-specific nucleases. Crystallographic studies of R.BfiI revealed a three-dimensional fold that is different from the above examples. This enzyme belongs to the PLD superfamily, which includes enzymes of phospholipid metabolism, nucleases, as well as ORFs of unknown function in viruses and pathogenic bacteria. These enzymes are characterized by the invariant sequence motif, H(X)K(X)₄D. Crystal structure, mutagenic analysis, and *in silico* modeling of a Type II REase, R.PabI, revealed that the protein adopts a novel fold referred as a ‘HALF-PIPE’ domain. The PLD and HALF-PIPE domain-containing REases are metal-ion independent enzymes.

The hydrolysis of the phosphodiester bond consists of three major steps: generation of the attacking nucleophile, transition state formation-stabilization, and protonation of the 3' hydroxyl group. These reaction steps are similar to those of DNA transaction enzymes that synthesize nucleic acids in which the phosphoryl group is transferred to a growing phosphoryl ester. The general mechanism for the phosphodiester bond hydrolysis/formation in nucleic acids has been shown to be the S_N2 type, which involves an overall inversion of the stereochemical configuration of the tetrahedral phosphorous atom. Divalent metal ions play a major role at one or more steps during phosphodiester bond hydrolysis. Different metal ion mechanisms have been proposed for a variety of REases, involving one, two or three metal ions. In contrast to the S_N2 mechanism of PD-(D/E)xK, HNH and GIY-YIG family of REases, the PLD and HALF-PIPE REases seem to utilize ping-pong and β -elimination reaction chemistry respectively, for DNA cleavage. More structural studies are required to establish the catalytic mechanism for these enzymes.

Engineering Specificity: Chimeric and Synthetic Enzymes

In spite of having a large repertoire of sequence specificities, altering the specificity of REases (especially Type II), as well as engineering specificities, has been a major research goal. Such studies were facilitated by the detailed characterization of a number of

Table 3 Active site and mechanism of DNA cleavage in REases

Superfamily ^a	Example	Divalent cation	DNA cleavage	Base flipping	Active site core	Chemistry
PD-(D/E)XK	EcoRI	Yes	phosphodiester	Yes (Ecl18kl, EcoRII)	$\alpha\beta\beta\beta\alpha\beta$	S _N 2
HNH	KpnI	Yes (diverse)	phosphodiester	ND	$\beta\beta\alpha$	S _N 2
PLD	BfiI	No	phosphodiester	ND	α/β fold	Ping-Pong
GIY-YIG	Hpy88I	Yes (diverse)	phosphodiester	ND	α/β fold	S _N 2
HALF-PIPE	PabI	No	N-glycosidic	Yes (PabI)	α/β half barrel	β -elimination

^aSuperfamily is named after important residues in the active site except in the case of PLD (phospholipase D) and HALF-PIPE (see text).

ND – not determined, REase – Restriction endonuclease.

enzymes and the availability of structural information. The approaches involved were random mutagenesis followed by *in vivo* selection strategies to generate changed specificity. In parallel, site-directed mutagenesis approaches were employed to rationally design new specificities relying on the structural information about the REase-DNA complexes to generate different contacts. Other efforts included strategies to lengthen the recognition sequences and generate hetero-dimeric enzymes. While a number of attempts provided interesting insights and some success in generating highly specific nickases, an engineered, efficient REase with a new sequence specificity has, so far, not met with success.

An alternate approach, to generate chimeric endonucleases having a longer recognition sequence, was conceived to target large eukaryotic genomes. Type II REases having typical recognition sites of 4–8 bp would cut DNA once every 4096–65,536 bases. For genome engineering, enzymes that recognize sequences of 16–18 bp in length are needed to make a unique targeted double-strand break (DSB). Work on FokI, a Type IIS REase showed that it possesses separate DNA recognition and endonuclease activity domains. The bipartite nature of the FokI endonuclease suggested that it might be feasible to construct chimeric nucleases having novel sequence-specificities by linking other naturally occurring DNA-binding proteins to the cleavage domain of FokI endonuclease. This proved to be the case. Chandrasegaran and co-workers constructed the first ‘chimeric’ REase by linking the Ubx homeodomain from *Drosophila* to the FokI REase cleavage domain. They then created other novel site-specific endonucleases by linking different DNA-binding motifs, namely the helix-turn-helix motif, the zinc finger motif and the basic helix-loop-helix protein containing a leucine zipper motif. Since, engineered nucleases can further be altered experimentally, this foundational work established the potential for inducing targeted recombination in a variety of organisms and ushered in the era of genome engineering.

Taking a cue from this approach, Transcription Activator-Like Effector Nucleases (TALENs) were developed that were fusions between transcription factors and REases. TALENs comprise a nonspecific DNA-cleaving nuclease fused to a DNA-binding domain that can be easily engineered so that these nucleases can target essentially any sequence. The capability to quickly and efficiently alter genes using TALENs promises to have a profound impact on biological research and to yield potential therapeutic strategies for genetic diseases.

Bacteria and archaea have evolved an adaptive defense mechanism that uses a CRISPR-Cas system to degrade complementary sequences present within invading viral and plasmid sequences. The type II CRISPR/Cas system (the simplest of the three involving one Cas9 and two RNA components) relies on integration of foreign DNA fragments into CRISPR loci. Upon transcription and processing, these inserts produce short CRISPR RNAs (crRNAs), which then anneal to a *trans*-activating crRNA (tracrRNA), enabling CRISPR-associated (Cas) proteins to direct sequence-specific degradation of the foreign DNA. To generate a nuclease with a given 20 bp specificity, fusion of a specific 20 bp sequence followed by 3 nucleotides NGG (PAM or Proto-spacer Adjacent Motif) with the tracrRNA directs the Cas9 to that specific locus. As the Cas9 enzyme utilizes two different active sites (HNH and RuvC) for generating double strand breaks, variations in Cas9 involving one active site mutated are also used. In addition, variations involving Cas9 enzymes having different PAM sites, such as Cpf1 which recognizes TTV (V – A/C/G), are also used. The easily programmable RNA-guided nucleases from CRISPR-Cas systems are regarded as the most reliable tools for genome editing and engineering.

Arms Race-Evolutionary Pressure for Phages and Bacteria Evolve New Anti-Restriction Systems and REase Specificity

The rudimentary mechanism for self and non-self discrimination has a built-in vulnerability to host mimicry evasion paradigms. Further, exogenous DNA often bypasses restriction if it arrives pre-methylated (for example, through modification in a neighboring cell possessing the same MTase). The methylated foreign DNA is tolerated as a self-component and recognized by the host MTase during subsequent rounds of replication. Therefore, an invading genome can propagate freely in spite of REase surveillance once it manages to achieve methylation.

Evolution of new R-M specificities and the ways in which invading genomes escape or counter host defense strategies have been the subject of detailed investigation in a few model systems. Study of interactions between *E. coli* and coliphages and encounters of *Bacillus subtilis* with a number of its phages have provided instructive examples of the “war” between the host and the infecting viral particles. Table 4 provides a summary of various anti-restriction strategies employed by phages. The mechanisms range from mutational alterations in the enzyme recognition sites, a variety of DNA modifications, overcoming enzyme action by avoiding the cleavage, countering REase action by encoding neutralizing proteins, DNA substrate mimicry, degradation of essential co-factors needed for enzyme activity and many less understood mechanisms, underscoring the success of phages in outnumbering bacteria in nature (Table 4). On the bacterial part, although they appear to be on the losing side, a number of strategies have either evolved or been acquired through horizontal gene transfer. Table 5 provides a summary of the various nuclease-dependent anti-phage strategies. Thus in many bacteria, in addition to chromosomally encoded R-M systems, plasmid and phage encoded R-M systems have been acquired. Notably, even the complex Type I enzymes are transmitted by plasmids. Many of the plasmid-encoded enzyme modules fit into the description of addiction modules, as their “selfish behavior” has been demonstrated. Thus, it is no surprise that many bacteria exhibit more than one kind of R-M system (Type I, II) while some even possess several systems of the same group, strengthening their armory against invasion.

On yet another front, several strategies are found in nature to evolve new R-M specificity. Genetic recombination within *hds* genes, transposition, slippage synthesis, and mutational events are some of the mechanisms that generate new enzyme specificities. Evolution of modification-dependent REase systems (Type 4) is yet another formidable strategy developed by bacteria against phages that had evolved the ability to by-pass restriction by modification of their genomes. Further, a number of REases do not

Table 4 Bacteriophage anti-restriction strategies

Phage strategy	Examples	Remarks/characteristics
Phages encoding MTases	Phages SPR, Ψ 3T, δ I1, and SP β that infect <i>Bacillus subtilis</i>	Acquired from host-encoded MTases
Complex genome modification	Glycosylation (Phage T _{even}), hydroxymethylation (Phage T _{even}), Acetamidation. Mommification by transfer of acetamide group to N ⁶ position of adenine in phage Mu	Repurposing of non-nucleic acid enzymes
Depletion of co-factor	Adomet hydrolase (phage T3)	Targets Type I R-M system
Loss of R-M recognition sites	Under-representation of CCGG, GGCC and CGCG in phage PZA	Palindrome sequence avoidance is the oldest outcome of selection in phages
Exploitation of cleavage mechanism of Type III R-Ms	Strand bias of EcoP1I sites in phage T7 genome	Type III methylase utilizes the same mechanism of single-stranded asymmetric host methylation to protect genome
Genome level changes	Single stranded DNA genome to avoid REases	Broad anti-restriction strategy against REases
Hyper-activation of MTase	ral gene (phage I) activates MTase of Type I R-M	Ral induces conformational change in hsdMS
Hacking bacilli cell architecture	Phages T4, T7, KVP40, P1, and A1122 localize to poles	Not supported by experimental evidence

REase – Restriction endonuclease, MTase – Methyltransferase, R-M – Restriction modification systems, Adomet – S-Adenosyl methionine.

Table 5 Anti-phage mechanisms involving degradation of phage genomes

Bacterial strategy	Example	Targeted phage anti-restriction strategy
Modification specific REases	Type IV REases such as McrBC	Targets phage acquisition of genome modification mechanisms
Altering R-M specificity	<i>Lactobacillus lactis</i> alters specificity by recombination of two HsdS subunits	Counters the decrease in specific restriction sites
Type II REase DNA cleavage promiscuity	Ability to recognize and cleave recognition site differing in single base	Counters the decrease in specific restriction sites
Phase variation	<i>Streptomyces coelicolor</i> undergoes phase variation to limit Phage fC31 population	High frequency on or off switching mechanism to prevent phages from developing anti-restriction strategy
Antisense mechanism	<i>Rhodobacter sphaeroides</i> argonaute protein targets plasmid-encoded genes	Broad strategy against foreign plasmids
CRISPR-Cas system	Widely distributed in bacteria and archaea	Provides acquired resistance mechanism

REase – Restriction endonuclease, R-M – Restriction modification systems, CRISPR – Clustered regularly interspaced short palindromic repeats.

appear to be exquisitely sequence-specific, as originally described. Recent studies reveal that many of the Type II enzymes exhibit promiscuous activities. Promiscuity in REases provides an upper hand to the organism to restrict incoming DNA even if the phages have evolved the strategy of palindromic avoidance (i.e., mutation in canonical recognition sites). Above all, a number of diverse CRISPR-Cas systems have evolved at a later stage after the initial escape and success of the phages against the host REases. However, strikingly, novel hitherto unexpected anti-CRISPR mechanisms are also being discovered. Thus, there is a continuum of evolving mechanisms, both on the host front and with the invading genomes.

R-M Systems and Phase Variation

Phase variation is a process by which bacteria undergo frequent and reversible genotypic changes in specific genes that impart phenotypic changes in organisms. Phase variation has been shown to help pathogenic bacteria in colonization and evasion of host immunity. The main mechanism of phase variation involves insertion or deletion of polyG or polyC repeat tracts in ORFs during genome replication. While phase variation is typically associated with genes encoding surface antigens, several host-adapted bacterial pathogens have MTases (*mod* gene), belonging to Type III R-M systems, that contain single tandem repeats that are prone to phase variation.

In every case studied to date, phase-variable ON/OFF switching of the Type III DNA MTase is mediated by a simple sequence repeats that results in differential regulation of multiple genes. Currently, the well characterized “phase-varions” and *mod* genes include *modA* in non-typeable *Haemophilus influenzae* (NTHi), *Neisseria meningitidis*, and *Neisseria gonorrhoeae*; *modB* in *N. meningitidis* and *N. gonorrhoeae*, *modD* in *N. meningitidis*, *modH* in *H. pylori*, and *modM* in *Moraxella catarrhalis*. The list of phase-variable DNA MTases controlling phase varions is expanding, with many new systems characterized within the past few years

(Table 6). The identification of a variety of phase-variable MTases that switch their expression *via* distinct mechanisms, implies that phase variations have evolved independently in different species and suggests that this type of variable epigenetic regulation provides a strong selective advantage. The random and reversible switching of phase-variable DNA MTase leads to multiple distinct phenotypes in a population that is subject to periodic selection and counter selection in different environments.

R-M Systems are More Than a Bacterial Defense Strategy

Perhaps only a few groups of enzymes have manifested such a large diversity in number and variation as is seen in R-M systems. However, the estimate that there are 10^{21} phages against 10^{19} bacterial species underscores the fact that invading genomes may have been more successful in their evasive strategies against host defense mechanisms. Now it is becoming increasingly clear that the large diversity may have also culminated in evolving other roles for these versatile enzymes given that the defense provided by them is not fool-proof. Further, many of the REases do not appear to have high turnover. If some of the early biochemical studies were to be

Table 6 Phase variable DNA MTases

Table 7 Biological functions of R-M systems

<i>Function</i>	<i>Characteristic</i>	<i>Mechanism</i>	<i>Examples</i>
Phage restriction	Serves as host defense mechanism against phages	Foreign DNA cleavage	All R-M systems
Selfish genes	To promote survival and frequency of R-M systems	Post-segregational killing	Bsp6I, EcoRI, EcoRII, EcoRV, PaeR7I, PvuII, SsoI
Stabilization of genomic islands	To stabilize neighboring genomic regions	Post-segregational killing	Not supported by evidence
Programmed cell death	Stationary phase induced cell death for long time survival	Promiscuous activity and lower methylation	KpnI
Bacterial autoimmunity	Stochastic self restriction shaping adaptive evolution	Occasional cleavage of self DNA	EcoRI
Role in nutrition	Re-allocation of host resources to the virus	Degradation of host DNA	Chlorella and Marseille virus
Maintenance of species identity	Immigration controllers	Restriction of horizontal transfer of DNA	Type I and Type IV R-Ms of <i>Staphylococcus aureus</i>
Recombination/Genome rearrangements	Enhancement of recombination by REases	Foreign DNA restriction generates recombination compatible products	EcoKI REase
Genetic variation	C-T variations	Deamination of 5-methyl cytosine to thymine	HpaII MTase
Adenine methylation	Altered gene expression caused by epigenetic modification	Effects transcription	m ⁶ A MTases
Virulence	Effects virulence gene expression	Variable	R-M systems of <i>H. pylori</i>

R-M – Restriction modification, REase – Restriction endonuclease, MTase – Methyltransferase.

taken as pointers, Type I enzymes may not turn over at all. Many Type III enzymes also appear to function in a similar fashion, although, after the initial cleavage, the DNA could be the target of cellular exonucleases. The biological fitness for a bacterium having an active R-M system has been debated. Restriction site avoidance and expending too much energy for DNA hydrolysis in addition to complex organization escalate the cost/benefit ratio. Moreover in bacteria such as *H. pylori*, many putative R-M systems appear to be non-functional. The inadequacy of cellular defense manifested by R-M systems may have led to the evolution of CRISPR-Cas systems to better counter the invading genomes. These observations, taken together, suggest the possibility that R-M systems indeed may participate in other cellular functions. Indeed, now it is apparent that they participate in a variety of processes, such as providing nutrition, cellular apoptosis, maintenance of species identity, genomic rearrangement and recombination, autoimmunity, selfish behavior, maintenance of genomic islands, and possibly other yet unidentified roles (Table 7). What is not clear is whether these functions are moonlighting functions or in some cases, the R-M system may have ancestrally possessed these abilities even before becoming a *bona fide* R-M entity. Often some of these additional properties may be crucial for the bacteria to survive under extreme stress conditions or circumstances not conducive for normal growth.

Concluding Remarks and Future Considerations

In addition to the information explosion and conceptual break-throughs summarized above, R-M systems have long been integral tools of modern biological research. Engineering novel REase specificities and development of Zinc-finger nucleases have allowed TALENs to pave the way for genome engineering. With the discovery of CRISPR-Cas systems, there has been a quantum leap in new technologies in the area of gene targeting, genome engineering and allied fields. Little did one realize that these adaptive immune strategies could be exploited in modern biological research in such a short time. Moreover, conventional R-M tools along with emerging tools based on CRISPRs, offer many opportunities in the area of synthetic biology. In nature, the arms race will continue and new mechanisms will be discovered, thereby providing opportunities for new technologies to emerge. Admittedly, among the vast diversity of R-M systems, a select minority has been subjected to intense examination. With the explosion of genomic data, more varieties are likely to be discovered. Meanwhile the large pool available provides opportunities to construct hybrid enzymes and engineer specificities tailored for specific purposes. It is apparent that CRISPR-Cas technologies will be further refined. Newer and much improved efficiency can be achieved with shorter Cas 9 (natural or engineered) proteins. Given the enormous pool, it is probable that other moonlighting functions of R-M systems would be uncovered. Cas genes could be engaged in other cellular functions as well. Further, surveillance provided by both R-M and CRISPR-Cas systems can be programmed for selective incorporation of genes that would reduce the risks of parasitism and immunopathology. They can also be possibly engineered to induce regulated programmed cell death in treatment strategies. Such an approach would be useful in dealing with microbial infections.

Although R-M systems and CRISPRs form a formidable combination of self-defense against infecting phages, they can be antagonistic to each other in certain situations. There could be some natural barriers for the acquisition of additional R-M or CRISPR-Cas systems. For example, although natural transformation is not obstructed normally by a resident R-M system in

Pneumococcus, resident CRISPRs form a barrier against the process and affect virulence. Such studies will be invaluable in understanding genome dynamics and evolution in bacteria. Among the interesting future experiments will be the construction of a synthetic genome having representatives of all 4 types of R-M systems as well as different kinds of CRISPR-Cas to evaluate the efficiency of such “super bacteria” against a few phages that have developed elaborate anti-restriction and anti-CRISPR strategies. Further, the *Helicobacter*, *Neisseria* and *Bacillus* genera are unlikely to be the only examples carrying a large number of R-M systems. Search in the genome databases, which have been expanding, is likely to reveal newer genomes with a bagful of R-M systems.

In summary, the fundamental research and understanding of R-M systems and CRISPRs is far from over. The current knowledge base provides a platform to develop newer, improved technologies, while understanding the characteristics of the new enzymes. Sequencing of more bacterial and phage genomes is likely to reveal more surprises. These efforts will provide better insights into bacterial and viral genome dynamics, interplay, and evolution that will open up avenues for developing new tools for synthetic biology approaches. The emergent information on R-M systems, anti-restriction mechanisms, and CRISPRs emphasize the fast paced evolutionary dynamics of the microbial world.

Retroviruses[☆]

Hung Fan, University of California, Irvine, CA, USA

© 2019 Elsevier Inc. All rights reserved.

Glossary

Endogenous retroviruses DNA forms of retroviral DNA that are vertically transmitted; they are present in the genomic DNA. They represent infection of retroviruses into the germline during evolution of a species. Most eukaryotes (including humans) carry multiple copies of endogenous retroviral DNA.

Exogenous retroviruses Retroviruses that replicate by passage from one cell to another – typical infectious retroviruses. They are not endogenous retroviruses.

Polyprotein Initial viral translation products contain the peptide sequences for multiple viral proteins. These are referred to as polyproteins. Nomenclature for polyproteins includes the molecular mass (in Kd) as well as the gene encoding the polyprotein – for example Pr65^{gag}. Polyproteins are cleaved into the mature proteins by viral or cellular proteases.

Retrovirus Enveloped RNA-containing viruses that carry the enzyme reverse transcriptase in their virions. Synthesis of viral DNA from the viral RNA and integration of the viral DNA into the host cell chromosomes are characteristic features of these viruses.

Classification

Retroviruses of higher eukaryotes (family *Retroviridae*) are classified by the International Committee on Taxonomy of Viruses (ICTV) based on their phylogeny and molecular biology into two subfamilies, orthoretroviruses (*orthoretrovirinae*) and spumaviruses (*spumaretrovirinae*) (Table 1). They have also been termed simple retroviruses if their genomes contain only the standard three viral genes (*gag*, *pol* and *env*); complex retroviruses carry additional viral genes. Within the orthoretroviruses there are six genera, five of which are associated with development of cancers. Alpharetroviruses are simple retroviruses native to birds (e.g. avian leukosis virus of chickens), and they were the first retroviruses discovered – predominantly in chickens, where they cause leukemias and sarcomas. Betaretroviruses have been found in several different species, including mice (murine mammary tumor virus [MMTV]), monkeys (Mason-Pfizer monkey virus [MPMV]) and sheep (jaagsiekte sheep retrovirus [JSRV]); they cause carcinomas of the breast (MMTV) and lung (JSRV). Gammaretroviruses are simple viruses that have been found in mice, cats, birds and gibbon-apes (e.g. murine leukemia virus [MuLV], reticuloendotheliosis virus [REV], feline leukemia virus [FeLV] and gibbon-ape leukemia virus [GaLV] respectively). They cause different kinds of leukemia. Deltaretroviruses are complex retroviruses associated with development of lymphoid leukemias in humans and cattle (human T-cell leukemia virus [HTLV] and bovine leukemia virus [BLV] respectively). Epsilonretroviruses are native to fish (e.g. walleye dermal sarcoma virus [WDSV]), and they have transduced cellular genes such as cyclins; they cause sarcomas and epithelial tumors. Lentiviruses are complex retroviruses native to several species including sheep, goats, old world monkeys and humans (e.g. maedi/visna virus of sheep [MVV] and human immunodeficiency virus [HIV]). Lentiviruses are associated with development of immunodeficiency and neurologic symptoms – the long latency for disease development gave these viruses the name ‘lenti’. The spumavirus subfamily contains one genus, foamy viruses (e.g. simian foamy virus) which are complex retroviruses characterized by strong cytopathic effects when they infect cells in culture (intense cytoplasmic vacuolization leading to a ‘foamy’ appearance). However, they are not associated with disease. Foamy viruses differ from other retroviruses with regard to several features of their replication, most notably the fact that virions contain reverse-transcribed viral DNA.

Structure

Retroviruses are enveloped RNA-containing viruses with single-stranded RNA as their genetic material (Figure 1). The viral RNA resembles a cellular messenger RNA in that it is capped at the 5′ end and polyadenylated at the 3′ end. It is positive-stranded, in that the viral RNA is the same polarity as viral mRNA. There are two identical copies of viral RNA in each virion, and they are held together by hydrogen-bonding in a parallel fashion near their 5′ ends (the ‘dimer linkage’). Retroviral genomes range from 7–12 kb in length. All retroviral genomes contain three genes: *gag* (encoding the proteins of viral core or capsid), *pol* (encoding the viral enzymes) and *env* (encoding the viral envelope proteins).

Table 1 Retrovirus classification.

<i>Subfamily</i>	<i>Genus</i>	<i>Representative species</i>	<i>Host species</i>	<i>Diseases</i>	<i>Extra genes (beyond gag-pol-env)</i>
Orthoretrovirinae	Alpharetrovirus	Avian leukosis virus (ALV)	Chicken	B-lymphoma	
		Rous sarcoma virus (RSV)	Chicken	Sarcoma	
	Betaretrovirus	Murine mammary tumor virus (MMTV)	Mouse	Breast cancer	Sag, Rem
		Mason-Pfizer monkey virus (MPMV)	Monkey		
	Gammaretrovirus	Jaagsiekte sheep retrovirus (JSRV)	Sheep	Lung cancer	Rej
		Murine leukemia virus (MuLV)	Mouse	Leukemias	
		Feline leukemia virus (FeLV)	Cat	Leukemia	
		Gibbon-ape leukemia virus (GaLV)	Gibbon	Leukemia	
		Reticuloendotheliosis virus (REV)	Chicken	Immunosuppression, lymphomas	
		Koala retrovirus (KoRV)	Koala	Leukemia	
	Deltaretrovirus	Human T-cell leukemia virus (HTLV-I and -II)	Human	T-cell leukemia HAM/TSP (HTLV-I)	Tax, Rex, others
		Simian T-cell leukemia virus (STLV)	Old World monkeys		Tax, Rex, others
	Epsilonretrovirus	Bovine leukemia virus (BLV)	Cow	B-cell leukemia	Tax, Rex, others
		Walleye dermal sarcoma virus (WDSV)	Walleye pike	Dermal sarcoma	Orf A (retroviral cyclin), Orf B, Orf C
	Lentivirus	Maedi/visna	Sheep	Neurodegeneration, pulmonary disease	Tat, Rev, Vif
		Human immunodeficiency virus (HIV-1 and -2)	Human	Immunodeficiency Neurologic disease	Tat, Rev, Nef, Vif, Vpu, Vpr
		Simian immunodeficiency viruses (SIVs)	Old World monkeys	Immunodeficiency (nonnative hosts)	Tat, Rev, Nef, Vif, Vpr, Vpx
		Feline immunodeficiency virus (FIV)	Cat	Immunodeficiency	Tat, Rev
		Equine infectious anemia virus (EIAV)	Horse	Anemia	Tat, Rev, S2
		Caprine arthritis encephalitis virus (CAEV)	Goat	Arthritis encephalitis	Tat, Rev, Vif
Spumavirinae	Spumavirus	Simian foamy viruses	Nonhuman primates		Tas, Bet
		Foamy viruses of nonprimates	Cow Horse Cat		Tas, Bet

Retroviral envelopes consist of viral protein embedded in cell-derived lipid bilayer. The viral envelope proteins consist of SU and TM. These proteins are glycosylated, predominantly with N-linked carbohydrates. SU (surface, ~70 – 120 Kd depending on virus) is on the surface of the virus particle and it contains the receptor binding domain (RBD) that is responsible for specific attachment of the virus to a susceptible cell at the beginning of infection cycle. The attachment of the virus particle to a cell is mediated by binding of the SU RBD to a receptor molecule on the surface of the infected cell. Different retroviruses have evolved to recognize different cell surface molecules as receptors, and the types of cells or tissues that can be infected *in vivo* is restricted to those cells/tissues that express the receptor. SU is anchored to the virus particle by interaction (typically disulfide bonds) with the transmembrane protein (TM, ~15 – 45 Kd); TM spans the lipid bilayer of the envelope. The external domain (ectodomain) of TM contains sequences involved in formation of envelope multimers (trimers), as well as sequences that mediate fusion of viral and cellular membranes during infection. The C-terminus of TM contains a short stretch of polypeptide that is on the interior of the viral envelope (or in the cytoplasm of the infected cell). These residues may interact with viral Gag protein to localize Gag to areas of the infected cell membrane where virus particle formation occurs. The envelope proteins are initially translated as one combined polypeptide (polyprotein), with SU at the amino terminus and TM at the carboxyterminus. Cleavage is carried out by a cellular protease (typically furin) during passage through the RER.

The viral core is a condensed structure consisting of viral core proteins, viral enzymes, the genomic RNAs and cellular tRNAs. The viral core proteins consist of matrix (MA, lying under the envelope ~10-15 Kd), major capsid (CA, the structural protein of the viral core particle, ~25-30 Kd) and nucleocapsid (NC, that binds and compacts viral RNA, ~10 Kd). There are approximately 1000 of each core protein in a retrovirus particle. In addition depending on the virus, other proteins are also encoded by *gag* and are present in virions (e.g. p12 of MuLV and p6 and p1 of HIV). When retroviral cores are first assembled, they have spherical symmetry; in their mature condensed forms, some cores are condensed and roughly spherical, while mature lentiviral cores are conical. The fundamental viral capsid structure consists of hexagonal arrays of CA protein, with a smaller number of pentagonal arrays. However retroviral capsids do not have uniform structures such as icosahedrons.

Figure 1 Retrovirus structure. Schematic structure of a retrovirus virion is shown at the top. The organization of genomic RNA (from 5' to 3') is shown for a simple retrovirus, with the locations of the different viral genes and coding regions indicated. Reverse transcribed viral DNA is shown relative to viral RNA, with the long terminal repeats (LTRs). The regions of the viral RNA encoding different portions of the LTR are indicated (dotted lines). An LTR is shown in greater detail at the bottom, with the enhancer, promoter, and cleavage/polyadenylation signals.

The viral enzymes consist of reverse transcriptase (RT, ~80 – 120 Kd), integrase (IN, ~30-40 Kd) and protease (PR ~10-12 Kd). Depending on the virus, the RT enzyme consists of monomers (MuLV) or heterodimers in which one subunit lacks C-terminal sequences (e.g. the p66/55 complex of HIV RT). There are approximately 50–100 copies of the viral enzymes in a virus particle. They carry out essential steps in retroviral replication, as described below. The *gag* and *pol* genes also are initially translated as polypeptides, followed by proteolytic cleavage during maturation to give the final proteins in the virus particles. Proteolytic cleavage of the *pol* polypeptide is required for enzymatic activities of RT, IN and PR.

For complex retroviruses, the additional genes carry out various functions. One common type of additional gene encodes a transcriptional transactivator that stimulates transcription from the viral LTR. Such transactivating proteins include HIV Tat, HTLV-I Tax and foamy virus Bel-1. Another common additional retroviral gene encodes a factor that facilitates nuclear export of unspliced viral RNA from the nucleus to the cytoplasm and/or efficiency of translation (e.g. HIV Rev, HTLV-I Rex, MMTV Rem and JSRV Rej). Other proteins encoded by complex retroviruses counteract host resistance mechanisms to retroviral infection (e.g. HIV-1 Vif and Vpr – see below).

Retroviral replication

The retroviral replication cycle is described in this section (Figure 2). The first step in retroviral replication is binding of a virion to the surface of the target cell. This is mediated by a specific interaction between the RBD of the SU protein and receptor molecule on the surface of the target cell. Retroviruses have evolved to recognize a wide variety of cell surface proteins as receptors. These include multiple pass membrane spanning proteins that function as transporters (e.g. amino acid and phosphate transporters for different MuLVs), single-pass membrane-spanning proteins (e.g. a member of the TNF receptor family for subgroup B avian leukosis viruses) and proteins that are on the cell surface (e.g. the CD4 protein for HIV). The tissue distribution of virus receptor molecules determines the cells or tissues that the virus can potentially infect. For instance, the CD4 receptor for HIV-1 is predominantly present on T-helper lymphocytes, macrophages and dendritic cells; thus these cells are the primary targets for infection in vivo. In the case of HIV-1 and related simian lentiviruses, successful infection requires interaction with both CD4 as well as a co-receptor (the chemokine receptors CCR5 for CXCR4 for HIV-1).

Once the virus has bound to the cell, the viral core enters the cytoplasm (viral entry). For some retroviruses, this may occur at the cell surface by fusion between the viral envelope and the cellular plasma membrane. For other viruses, receptor-mediated

Figure 2 The retrovirus replication cycle. A cell undergoing infection is shown; the nucleus is shaded. Infection begins at the upper left, with binding of a virion to a receptor on the cell surface. Different steps in the infection process are described in the text. They culminate in release of immature virions by budding from the cell surface. Maturation involves cleavage of viral polyproteins by viral protease.

endocytosis of the entire virion may occur, followed by fusion within the lysosome of the viral envelope with the lysosomal envelope. The membrane fusion is mediated by the TM protein, which undergoes a major conformational shift that brings the cellular and viral lipid bilayers into such close proximity that they fuse. Membrane fusion leads to release of the core into the cytoplasm. The ectodomain of the TM protein mediates the membrane fusion.

Once the viral core is released into the cytoplasm, the enzyme reverse transcriptase in the core is activated. RT uses the viral RNA as a template to synthesize linear double-stranded viral DNA. RT has three enzymatic activities that are all important for synthesis of viral DNA: 1) RNA-dependent DNA polymerase (used in synthesis of the first [–] strand of DNA, resulting in an RNA-DNA hybrid), 2) DNA-dependent DNA synthesis (used in synthesis of the second [+] DNA strand), and 3) RNaseH that degrades RNA from an RNA-DNA hybrid. For initiation of synthesis of the first strand of viral DNA, RT requires a polynucleotide primer with a free 3' hydroxyl hydrogen-bonded to the viral RNA. The primers for retroviral reverse transcription are cellular tRNAs; different retroviruses employ different tRNAs. After reverse transcription, the resulting viral DNA is longer than the template RNA by carrying two copies of the same sequences (long terminal repeats or LTRs) at either end (Figure 1). Viral LTRs can be subdivided into three regions: the U3 regions are encoded in viral RNA uniquely at the 3' end, the U5 regions are encoded in viral RNA uniquely at the 5' end, and the

R regions are encoded in repeated sequences at either ends of the viral RNA. After reverse transcription, the viral DNA remains complexed with viral core proteins, most notably integrase.

After the viral DNA is reverse transcribed in the cytoplasm, it and its associated proteins (the pre-integration complex) enter the nucleus. For simple retroviruses such as MuLV, this process is dependent upon passage of infected cells through mitosis and the accompanying breakdown of the nuclear envelope. On the other hand, lentiviruses are able to transport their pre-integration complexes across the nuclear membrane via virus-encoded proteins (Vpr, IN and potentially MA proteins); thus these viruses can infect non-dividing cells. Once the pre-integration complex is in the nucleus, the viral DNA is inserted into host chromosomal DNA through the action of the viral integrase. During integration the two ends of the viral DNA are held together by the IN protein (multimer), and insertion is a concerted reaction where both ends of the DNA are integrated simultaneously. As a result of integration, two viral DNA nucleotides are lost at either end, and a short stretch of adjoining cellular DNA sequences (4–13 nucleotides depending on the virus) are duplicated at either side of the integrated viral DNA. This reflects the way that IN protein cleaves the host and viral DNAs during the integration reaction – ‘staggered cuts’ in both cases, followed by ligation of one strand of viral DNA to one strand of host chromosomal DNA. Cellular DNA repair enzymes then complete the process by removing unpaired nucleotides and filling in single-stranded regions, resulting in the viral nucleotide deletions and cellular nucleotide duplications. The integrated form of viral DNA is termed the provirus, and it resembles the linear reverse transcribed viral DNA. Integration of viral DNA into the host chromosomal DNA occurs at multiple (virtually random) sites. Within the context of these multiple insertion sites, for some retroviruses there is a bias for integration near the start sites of transcription (e.g. MuLV), for others there is a bias for integration generally within genes (e.g. HIV) and for others there is no bias for insertion sites (e.g. avian leukosis virus and MMTV).

Once integrated into the host DNA, the retroviral provirus is transcribed into viral RNA. Transcription is carried out by host cell machinery, including RNA polymerase II, the enzyme responsible for transcription of cellular mRNA precursors, as well as host enhancer-binding proteins. The retroviral provirus functions as a single transcription unit, with transcriptional control sequences contained within the LTRs. The U3 region contains a promoter (i.e. TATAAA at -30 bp) and upstream enhancer elements; transcription initiates at the U3-R boundary in the upstream LTR. The 3' end of the RNA is determined by a cleavage/polyadenylation signal in the R region of the LTR which leads to cleavage/polyadenylation of the RNA at the R-U5 boundary in the downstream LTR. The resulting transcript (capped at the 5' end and polyadenylated at the 3' end) is identical to genomic viral RNA present in the virion.

Some retroviruses encode viral transactivators that activate transcription for the viral LTR, including HTLV-I Tax and HIV Tat. The mechanisms of action are different, with HTLV-I Tax binding to cellular transcription factors (e.g. CREB) and potentiating the CREB binding to enhancer sequences in the LTR. In contrast, Tat binds to a 5' stem-loop in the 5' end of the viral transcript, which leads to recruitment of Cyclin T/CDK9 and associated proteins. This complex phosphorylates the C-terminal tail of RNA polymerase II, which enhances processivity of the enzyme and production of full-length viral transcripts. In the absence of Tat, transcription stalls after formation of the 5' stem-loop. Some retroviruses also carry additional internal promoters (e.g. MMTV and foamy viruses) or promoters on the opposite strand (HTLV-I).

The newly transcribed viral RNA in the nucleus is exported to the cytoplasm along two pathways. In one pathway, viral RNA with and without mRNA splicing is transported to the cytoplasm to function as mRNA. The viral mRNAs are translated by host cell ribosomes and translation factors. There are two forms of viral mRNA for simple retroviruses: unspliced RNA that is translated into Gag and Pol proteins, and a singly spliced mRNA that is translated into Env proteins (Figure 3). As mentioned above, each of the

Figure 3 Retroviral mRNAs. All retroviruses use two forms of viral mRNA: unspliced RNA is translated into Gag and Gag-pol polyproteins, and singly spliced RNA is translated in Env polyprotein. The positions of initiation codon (AUG) and termination codons (T) are shown on the unspliced viral RNA.

viral genes is translated as a single polypeptide. For unspliced viral mRNA, translation is initiated at the 5' end of the *gag* gene and the majority of translation products are terminated at 3' end of *gag* to give a Gag polyprotein (e.g. Pr65^{gag} for MuLV). Infrequently, (5–10% of the time) translation does not terminate at the end of the *gag* gene, and it continues into the *pol* gene, resulting in a Gag-Pol fusion polyprotein (Pr180^{gag-pol} for MuLV). For MuLVs, this results from translational suppression where the *amber* termination codon at the C-terminus of *gag* is suppressed by insertion of a glutamine into the growing polypeptide by a naturally occurring glutamyl suppressor tRNA. For other retroviruses, an RNA pseudo-knot in the vicinity of the Gag termination codon results in a –1 frameshift by the ribosome into the *pol* reading frame without release of the growing polypeptide chain. Cellular mRNAs typically require splicing for efficient export from the nucleus, and retroviruses have evolved mechanisms to facilitate export of unspliced viral mRNA to the cytoplasm. For complex retroviruses, virus-encoded proteins (e.g. HIV Rev) bind to the unspliced RNA and facilitate its nuclear export by interacting with cellular proteins involved in nuclear export (i.e. Crm-1). Simple retroviruses (e.g. MPMV, RSV) tend to contain constitutive cytoplasmic transport elements in their RNAs; these elements bind host cell factors (e.g. TAP/NXF1) that facilitate nuclear export of the unspliced viral RNA.

Once the viral polyproteins are translated, they combine with other unspliced viral RNA (from the second pathway) to form virus particles that bud from the cell surface. Core particles are assembled by Gag-Gag interactions among Gag (and Gag-pol) polyproteins, viral RNA may function as a scaffold in this process, through the RNA-binding capacity of the NC domain. Incorporation of viral RNA into particles requires specific sequences in the viral RNA (packaging site or Ψ sequences), typically located near the 5' end. If the Ψ sequences are deleted from a retroviral RNA, it will not be packaged. However, if Ψ + viral RNA is not available, cells expressing viral proteins will still assemble particles, incorporating cellular RNAs instead. For most retroviruses, assembly of virus particles and budding occurs at the plasma membrane. Interactions between the cytoplasmic tail of envelope TM protein and the amino terminal MA domain of Gag polyprotein serves to localize Env protein the region of virus budding. For some viruses (e.g. HIV), budding takes place in plasma membrane regions enriched in cholesterol (lipid rafts).

The assembly of retroviral particles can be visualized by transmission electron microscopy, typified by partially assembled crescent-shaped 'C-type' particles at the cell surface. However betaretroviruses assemble intact core particles intracellularly (B-type particles) at a perinuclear region (the microtubule organizing region), after which the cores are transported to the plasma membrane for budding. Another pattern of budding for retroviral particles is into intracisternal membranes (A-type particles). Recently, progress has been made in understanding the retroviral assembly process. In particular, cellular proteins involved in trafficking of protein cargoes between different cellular compartments (e.g. the Escort complexes) have been implicated. They interact with 'L - domains' present on the viral Gag proteins during these processes. Viral L-domains contain amino acid motifs such as PTAP and YPDL which serve as the binding sites for components of the Escrt complexes (e.g. Tsg101 binding of the HIV-1 Gag PTAP motif). Another feature of this assembly is that the Gag proteins become modified by the addition of mono-ubiquitin as a result of their interactions with the cellular proteins, some of which are ubiquitin ligases.

When retroviral particles are initially budded from the cell, they are immature. In particular, the Gag and Gag-Pol polyproteins have not been cleaved, and the immature cores consist of spherically symmetric arrays (hexagonal lattices) of Gag polyproteins along with Gag-pol polyproteins. Virion maturation is mediated by self-cleavage and activation of the viral protease (PR) from the Gag-Pol polyprotein; PR then cleaves the Gag and Gag-Pol polyproteins into the final mature proteins. Retroviral proteases are site-specific aspartyl proteases. PR cleavage of the Gag and Gag-Pol polyproteins into the mature virion proteins results in rearrangement of the core structure into a hexagonal lattice of mature CA protein hexamers containing twelve CA pentamers (that allow closure of the CA lattice into spheres or cones). This results in a condensed mature core that does not fill the entire volume of the original immature particle; ca. half of the Gag protein is not retained in the mature core. Particles with mature cores are infectious. PR cleavage of the Gag-pol polyprotein also results in activation of the RT and IN enzymatic activities. Gag and Gag-pol cleavage is essential for retroviral infectivity; HIV-1 antiviral drugs of the protease inhibitor class inhibit this process.

For most retroviruses, infection does not result in death (lysis) of the cell. Infected cells typically will continually produce virus particles. The fact that retrovirus-infected cells are not lysed can lead to oncogenic transformation of the infected cells and development of tumors. One exception to the general rule is HIV-1, which kills infected T-helper lymphocytes (but not infected macrophages or dendritic cells). The killing of T-helper lymphocytes by HIV-1 is important for the development of AIDS.

Retroviruses and disease

Cancer

Retroviruses first received attention because they can cause cancer. The first discovered retroviruses were those of chickens that cause leukemias (avian myeloblastosis virus) and sarcomas (Rous sarcoma virus, RSV). Oncogenic viruses have subsequently been discovered that infect a variety of higher eukaryotes including man. Oncogenic retroviruses can be divided into two categories, acute transforming retroviruses (Table 2) and non-acute retroviruses. They differ in their mechanisms of oncogenesis.

Acute transforming retroviruses cause tumors quite rapidly in experimental animals (mean times of disease in weeks-months), and they can frequently alter the growth properties of cells in culture (transformation). The altered growth properties include many properties associated with tumor cells, such as loss of contact inhibition, the ability to grow in suspension, and reduced requirements for growth factors. The common feature of acute transforming retroviruses is that they carry oncogenes. These viral

Table 2 Representative acute transforming retroviruses and their oncogenes.

<i>Virus</i>	<i>Host species</i>	<i>Disease</i>	<i>Viral oncogene</i>	<i>Proto-oncogene</i>	<i>Normal proto-oncogene function</i>
Rous sarcoma virus (RSV)	Chicken	Sarcoma	v-src	c-src	Tyrosine-specific protein kinase
MC29	Chicken	Myeloid leukemia	v-myc	c-myc	DNA binding protein/transcription factor
Avian erythroblastosis virus (AEV)	Chicken	Erythroid leukemia	v-erbA	c-erbA/thyroid hormone receptor	Hormone-dependent DNA binding protein
E26	Chicken	Erythroid leukemia	v-erbB	c-erbB/EGFR	Epidermal growth factor receptor tyrosine kinase
			v-ets	Ets-1	DNA binding protein/transcription factor
Avian myeloblastosis virus (AMV)	Chicken	Myeloid leukemia	v-myb	c-myb	DNA binding protein/transcription factor
Reticuloendotheliosis virus -T (REV-T)	Turkey	Reticuloendotheliosis	v-rel	c-rel	NF KappaB subunit
S17 sarcoma virus	Chicken	Sarcoma	v-jun	c-jun	DNA binding protein/AP-1 transcription factor
Harvey murine sarcoma virus	Mouse	Sarcoma	v-ras ^H	H-ras	G-protein involved in signal transduction
Kirsten murine sarcoma virus	Mouse	Sarcoma	v-ras ^K	K-ras	G-protein involved in signal transduction
Murine sarcoma virus 3611	Mouse	Sarcoma	v-raf	c-raf	Serine/threonine protein kinase involved in signal transduction (MEKK)
Abelson murine leukemia virus	Mouse	B-lymphoma	v-abl	c-abl	Tyrosine protein kinase
AKT-8 murine leukemia virus	Mouse	T-lymphoma	v-Akt	Akt	Serine/threonine protein kinase in the PI3K signaling pathway
FBJ osteosarcoma virus	Mouse	Osteosarcoma	v-fos	c-fos	Component of AP-1 transcription factor (with c-Jun)
Feline sarcoma virus (McDonough strain)	Cat	Sarcoma	v-fms	c-fms/CSF-1R	Receptor tyrosine kinase; receptor for CSF-1

oncogenes (see Table 2) result from capture into the viral genome of normal cellular genes (proto-oncogenes). Viral oncogene proteins differ from the normal cellular proto-oncogene proteins. Depending upon the virus, the differences may be single amino acids substitutions (e.g. the *v-ras* proteins), truncation of regulatory sequences (e.g. *v-erbB*), or fusion with viral proteins sequences (e.g. Gag-v-Abl fusion protein encoded by Ab-MuLV). The viral oncogene proteins stimulate cell growth and division in an unregulated manner, unlike their cellular counterparts. Moreover, the viral oncogenes are under transcriptional control of the viral LTR, which leads to high level constitutive expression of the viral oncogene.

During the retroviral oncogene capture process, viral sequences are often lost. As a result, most acute transforming retroviruses are actually replication-defective, since they cannot encode some or all of the viral structural proteins. In order for them to propagate, co-infection with a related replication-competent retroviruses is required – these viruses are referred to as helper viruses. Infectious stocks of acute transforming viruses will consist of mixtures of an acute transforming retrovirus and a helper virus – sometimes identified as an ‘associated’ virus (e.g. Rous-associated virus [RAV] in Rous sarcoma virus stocks). In a co-infected cell, the helper virus will provide the structural proteins that package acute transforming retrovirus genomes into particles. Infection of such stocks at low multiplicity can yield transformed ‘non-producer’ cells that are only contain a genome for the acute transforming virus. These cells do not produce virus particles because they cannot encode the viral structural proteins, but they are transformed due to expression of the viral oncogene. Reinfection of transformed non-producer cells with a replication-competent virus can lead to production of infectious acute transforming retrovirus again.

Study of acute transforming retroviruses, their oncogenes and the corresponding cellular proto-oncogenes was key in uncovering basic processes in the molecular biology of cancer. In particular, many cellular proto-oncogenes originally discovered as cellular counterparts of viral oncogenes were later found to be activated in human tumors not induced by retroviruses. In addition, many cellular genes important in signal transduction, normal cell growth regulation and cancer were first discovered as the cellular proto-oncogene counterparts of retroviral oncogenes, for example *c-myc*, the *ras* genes, *c-raf*, *c-fos* and *c-jun* (Table 2). In general the normal function of proto-oncogenes is to stimulate cell growth or division in response to physiological signals. Signaling from normal cell proto-oncogenes is tightly regulated and transient.

One exception to the nature of retroviral oncogenes is found in jaagsiekte sheep retrovirus (JSRV, a betaretrovirus), the causative agent of a transmissible lung cancer in sheep (ovine pulmonary adenocarcinoma). JSRV is an acute transforming retrovirus in that induces lung tumors rapidly and it can transform cells in culture. Unlike for other acute transforming retroviruses, the viral oncogene is actually the viral envelope protein and not a captured version of a cellular proto-oncogene. The C-terminus (‘cytoplasmic tail’) of the TM protein is crucial for transformation, although other domains may be important as well. Expression of the JSRV Env protein alone is sufficient to induce tumors in several animal models.

Oncogenic **non-acute retroviruses** are typical replication-competent viruses lacking oncogenes. Nevertheless, they can induce tumors, although with longer latency than acute transforming retroviruses (months-years). A common feature of tumors induced by non-acute retroviruses is the presence of proviral DNAs inserted into the same chromosomal loci in different independently arising tumors (common insertion sites or CISs). This is noteworthy because of the random insertion of retroviral proviruses into host cell chromatin. The CISs represent selection in the tumors for cells that have sustained a viral integration at that particular site. The CISs have been found to contain proto-oncogenes or other genes whose normal functions are to positively signal cell growth and division. Proviral insertion leads to constitutive over-expression of the cellular proto-oncogene, which drives unregulated growth of the tumor cell. Multiple proto-oncogenes may be activated by a given retrovirus, and the spectrum of activated proto-oncogenes is characteristic of the particular retrovirus-tumor combination. An online database for proto-oncogenes activated in tumors induced by MuLVs is available (see Relevant Websites).

The insertional activation of proto-oncogenes occurs by two mechanisms (Figure 4). First, transcriptional readthrough can occur from the provirus into the proto-oncogene, often from initiation in the downstream LTR. This is referred to as the promoter insertion mechanism, and was first described for activation of the *c-myc* proto-oncogene in B-lymphomas induced by avian leukosis virus in chickens. Promoter insertion results in a fusion transcript between viral sequences and the proto-oncogene. This places the proto-oncogene under transcriptional control of the viral LTR, which leads to constitutive high level expression. In some cases, promoter insertion may occur within the introns of a proto-oncogene, leading to expression of a fusion transcript that encodes a truncated version of the proto-oncogene protein. In the second mechanism of LTR activation, enhancer sequences in the viral LTR activate the endogenous promoter of the proto-oncogene (enhancer activation). In this case, the proviral DNA may be inserted in the opposite transcriptional orientation from the proto-oncogene, or it may be situated downstream from the proto-oncogene. In tumors with LTR enhancer activation, fusion transcripts containing viral and proto-oncogene sequences are not observed; there is simply over-expression of the normal proto-oncogene transcript.

The slower rate of tumor induction by non-acute retroviruses can be rationalized. Since viral DNA insertion is essentially random in infected cells, the probability of a provirus integrating next to a proto-oncogene in a given infected cell is low. Multiple rounds of infection in an animal will be required before one cell sustains a proviral insertion in the vicinity of a critical proto-oncogene, in a configuration appropriate for activation. Once this occurs, then that cell will have enhanced replicative potential that can ultimately lead to outgrowth of a tumor.

Studies of CISs in retrovirus-induced tumors have led to the discovery of new proto-oncogenes. In some cases, some of these newly discovered genes have been found to be activated in non-virus induced tumors, including those from humans. Thus study of non-acute retrovirus-induced tumors has been a useful method of cancer gene discovery. Proto-oncogenes identified in this way include the Pim-1 kinase discovered in tumors induced by Moloney MuLV, and the Wnt-1 signaling proteins discovered in MMTV-induced tumors. Recently, high throughput techniques have been developed to increase the efficiency of proto-oncogene discovery, for instance in MuLV-induced leukemias. Inverse PCR (iPCR) is used to rapidly clone multiple proviruses (including adjacent cell DNA) from collections of tumors induced by an MuLV. The adjacent cell DNAs from the iPCR clones are sequenced and aligned with the mouse genome, which allows location of each provirus in the genome. Bioinformatics is then used to identify chromosomal loci where more than one provirus has integrated in the tumor collection. Currently retroviral

Figure 4 Oncogenesis by nonacute retroviruses. Transcriptional activation of cellular proto-oncogenes in tumors results from insertion of a retroviral provirus in the vicinity of the proto-oncogene. In promoter insertion, readthrough transcription from the viral LTR into the proto-oncogene leads to production of a fusion transcript. In enhancer activation the viral LTR enhancer activates over-expression from the proto-oncogene's own promoter. The over-expressed proto-oncogene transcripts are shown.

integration site analysis has been facilitated by high throughput DNA sequencing (deep sequencing) of virus-induced tumor DNAs.

For non-acute retroviruses, the viral LTRs play an important role in the disease specificity and efficiency of tumorigenesis. For instance, the Friend and Moloney strains of MuLV induce erythroid and T-lymphoid leukemias respectively. Exchange of LTRs between the two viruses is sufficient to reciprocally alter the disease specificities. In fact, exchange of just the U3 enhancer sequences between the two viruses is sufficient to change disease specificity. This can be understood in light of the importance of the LTR in proto-oncogene activation. In order for a non-acute retrovirus to induce oncogenic transformation of a cell, its LTR must be active in that cell type in order to activate an adjacent proto-oncogene. Indeed, the M-MuLV LTR is more active in T-lymphoid cells, while the F-MuLV LTR is more active in erythroid cells. It is interesting that any given non-acute retrovirus may activate a particular proto-oncogene or subset of proto-oncogenes when it induces tumors. This may reflect the relative importance of a particular proto-oncogene for development of tumors of a particular cell type, as well as the ability of enhancer sequences in a particular LTR to activate that proto-oncogene.

When tumors develop, multiple genetic and biochemical changes are necessary to convert a normal cell into the final tumor cell. This is also true for retrovirus-induced tumors. In tumors with one proto-oncogene activated by proviral insertion, presumably other non-viral secondary events occurred. In some cases the second events may also be induced by the retrovirus. For instance, more than one proto-oncogene may be activated by proviral insertion in the same tumor. Another example is Abelson MuLV, an acute transforming retrovirus carrying the *v-abl* oncogene that induces rapid B-lymphomas in mice. In order for Ab-MuLV to be tumorigenic, it requires M-MuLV as a helper, while other MuLV helper viruses are not effective. Ab-MuLV-induced tumors not only contain and express the *v-abl* oncogene, but they also have insertional activation of a proto-oncogene (*ahi-1* or *ahi-2*) by the helper virus (M-MuLV).

Immunodeficiency

Several retroviruses can induce immunodeficiency, most notably the lentiviruses HIV and related simian immunodeficiency viruses (SIVs). The SIVs are native to African old world primates, and in general they do not cause significant disease in their native species. However, when they infect other species, they can cause immunodeficiency. For instance, SIV_{mac} is actually native to African mangabeys, but when it infects Asian rhesus macaques it causes acquired immunodeficiency (simian AIDS). Likewise, HIV-1 is native to chimpanzees and HIV-2 is native to sooty mangabeys; both of these viruses have relatively recently entered the human population and they both cause AIDS while they have little or no effects on their native host species. HIV and AIDS is covered in more detail in another entry in this encyclopedia but some key points will be mentioned here. HIV-1 is the predominant cause of the worldwide AIDS epidemic, while HIV-2 induces AIDS less efficiently and is largely confined to Africa. Current estimates are that approximately 35 million people were infected by HIV worldwide at the beginning of 2012, with more than 90% of the infections in the developing world. Without treatment, most HIV-infected individuals will progress to clinical AIDS (severe immunodeficiency) with a latency of 10–15 years. Symptoms of AIDS include opportunistic infections (e.g. pneumocystis pneumonia [PP]), cancers (e.g. Kaposi's sarcoma [KS]) and neurological problems (e.g. dementia). The clinical definition of AIDS is HIV infection and one AIDS-defining illness (e.g. PP or KS) or CD4 T-cell counts below 200 mm⁻³ (normal CD4 counts are typically >1000 mm⁻³).

As mentioned above, HIV is a complex retrovirus with six additional genes (*tat*, *rev*, *nef*, *vpr*, *vif* and *vpu*). The CD4 receptor for HIV is present on T-helper lymphocytes, macrophages and dendritic cells, so these are the cells that can be infected *in vivo*. Infection of T-helper lymphocytes results in cell killing, while infected macrophages and dendritic cells are not killed. During the initial stages of infection, there is typically substantial loss of T-helper lymphocytes. The initial infection may be accompanied by flu-like symptoms, or it may be asymptomatic. Development of cell-mediated and humoral immune responses limits the initial infection, after which levels of circulating virus (viral loads) substantially decrease and T-helper (CD4) counts recover. The infected individual then enters an asymptomatic period (typically 8–10 years) where there are relatively low viral loads and relatively normal T-helper counts. However the infection has not been eliminated, as low levels of virus infection persist, and individuals continually produce virus-specific antibodies (the common diagnostic test for infection). Ultimately, the immune system is unable to control the viral infection, and rising viral loads result in progressive loss of T-helper lymphocytes. Since T-helper lymphocytes are essential for function of both cell-mediated immunity and humoral immunity, loss of T-helper lymphocytes leads to failure of both arms of the adaptive immune system. This results in the appearance of the symptomatic opportunistic infections and cancers.

One of the reasons that infected individuals cannot eliminate HIV infection is that the virus can establish latency – in latently infected cells the viral genetic information is present but virus is not produced. Latently infected cells can evade the immune system since they do not express viral proteins. Latently infected cells include macrophages and T-lymphocytes and they persist in infected individuals for many years. At later times they may be re-activated to produce virus that can spread. Another mechanism by which HIV evades host defenses is rapid and progressive mutation in infected individuals, particularly in the *env* gene. This mutation is largely driven by viral evasion of host immune adaptive responses (antibodies and cytotoxic T-lymphocytes) to the virus. In individuals being treated with anti-viral drugs, the high virus mutation rate also leads to development of drug-resistant virus. Temporal variation of HIV is also seen in infected individuals. The initial virus transmitted generally is one that uses the CCR5 co-receptor. With time, the virus will mutate so that it is more cyopathic (killing T-helper lymphocytes efficiently), which will often be accompanied by a switch to usage of the CXCR4 co-receptor.

Antiviral drugs targeted at HIV have substantially improved the clinical outlook for infected individuals. So far, antivirals targeted at RT, protease and integrase have been developed. RT inhibitors are divided into two classes, nucleoside reverse transcriptase inhibitors [NRTIs] and non-nucleoside reverse transcriptase inhibitors [NNRTIs]. NRTIs (typified by AZT) are chain-terminating nucleoside analogs that are incorporated by RT into viral DNA during reverse transcription; once incorporated, an NRTI cannot be further extended which kills the growing DNA molecule. The antiviral selectivity of NRTIs is due to the fact they are relatively inefficiently incorporated by host cell DNA polymerases. NNRTIs (e.g. nevirapine) inhibit reverse transcription by binding to RT and blocking its enzymatic activity. Additional drugs that block the initial entry events for HIV (fusion and co-receptor binding) have been developed and are available.

Prior to development of different classes of inhibitors, treatment with single HIV antivirals (NRTIs) proved to be of limited benefit. Monotherapy of infected individuals resulted in initial suppression of viral loads (with improvements in immune system function), but the effects were transient. Emergence of drug-resistant virus occurred quite quickly, with resulting decline in immune function. The development of additional classes of antivirals (notably protease inhibitors) paved the way for combination therapies. Combination therapies with several antiviral drugs are highly effective at reducing viral loads and improving the immune systems of individuals with AIDS. There are multiple combinations that are effective (some available as once-daily pills), and they always include inhibitors of more than one class. The reduction in viral loads can be prolonged, resulting in clinical improvement or even recovery in individuals with AIDS. However despite these very positive effects, combination therapies have limitations. The therapies must be taken continually since the virus has not been eliminated. Development of drug resistance is a major limiting factor, even for combination therapies. Clinical management of HIV-infected individuals includes monitoring for appearance of drug resistant virus and finding new combinations of drugs that control it. A second limitation is that many of the HIV antiviral drugs have side effects; this is particularly important because they must be taken continually to control the virus. Side effects include anemia, neuropathies, pancreatitis, diabetes, cardiac disease and lipodystrophy. The antiviral drugs are also expensive – beyond the means of many infected individuals in the developing world. For these reasons there is tremendous interest and effort in developing an effective preventative HIV vaccine. However efforts so far have not been successful.

In addition to HIV, other retroviruses also induce immunodeficiency in animals and they have been studied for insights into HIV pathogenesis. The most frequently studied animal retroviruses that cause immunodeficiency are simian lentiviruses (SIVs) infected into non-native primate species (e.g. SIV_{mac} into rhesus macaques). Simian retroviruses of the betaretrovirus class (simian retrovirus Type-D) also induce immunodeficiency in rhesus macaques. In addition, a murine retrovirus complex also induces murine AIDS (MAIDS). The MAIDS complex consists of an MuLV as well as a replication-defective MuLV derivative. The replication-defective component is responsible for the development of MAIDS. The mechanism of immunodeficiency is distinct from that associated with HIV infection, with the virus actually inducing proliferation of B-lymphocytes.

Neurologic disease

Several retroviruses also induce neurologic symptoms. HIV-infected individuals frequently develop such symptoms in the central nervous system (dementias) and in peripheral nerves (neuropathies). The dementias are associated with loss of neurons in the brain (spongiform encephalopathies) but the neurons themselves do not appear to be targets for HIV infection. Infection is observed in supporting cells, most notably microglial cells. Thus the mechanism of neuropathogenesis by HIV appears to be indirect. Some strains of MuLV also induce neurologic symptoms such as hind limb paralysis (in particular those derived from wild mouse ecotropic MuLV). These neuropathic strains of MuLV also induce spongiform encephalopathies of the brain or spinal cord. Similar to the situation with HIV, neuropathic MuLVs do not appear to infect neurons, so the pathogenesis likely results indirectly from infection of other cells.

The human retrovirus HTLV-I, which induces T-cell leukemia (see below) also induces a demyelinating disease known as HTLV-associated myelopathy or tropical spastic paraparesis (HAM/TSP). The symptoms resemble multiple sclerosis, and the disease may be immune-mediated.

Retroviruses of humans

While early research on retroviruses involved studies of animal retroviruses, several retroviruses of humans have been discovered, some of which cause disease. The first human retrovirus discovered was HTLV-I, which causes adult T-cell leukemia (ATL) and HAM/TSP. This virus is a member of the deltaretrovirus family, and it encodes several additional proteins from different reading frames in the X region. These include the transcriptional transactivator Tax and the Rex regulatory protein. Leukemogenesis by HTLV-I is relatively inefficient, with decades elapsing between infection and development of the leukemia. The Tax protein is likely involved in the process, since it can immortalize primary T-lymphocytes and transform fibroblasts in culture. Tax can transactivate cellular promoters in addition to the viral LTR, including the promoters for interleukin-2 (IL-2, T-cell growth factor) and the IL-2 receptor; the activation of these cellular genes may be involved in tumorigenesis. Simultaneous expression and IL-2 and IL-2R in a lymphocyte can lead to an autocrine loop in which there is continual signaling for cell division. On the other hand, many HTLV-induced ATL tumor cells actually do not express Tax, so Tax may be involved in establishment but not maintenance of the tumor. A more recently discovered protein is encoded by the opposite strand of HTLV-I, HBZ. This is a DNA binding protein with a B-zip

motif that can affect transcription of both HTLV and cellular genes negatively or positively. Moreover it is expressed in all ATL cells, which suggests that it is required for maintenance of HTLV-induced tumors. A virus related to HTLV-I, HTLV-II has also been isolated. HTLV-II has not been causally linked with any neoplasms, although it was first isolated from hairy cell leukemia cells (a form of T-cell leukemia). HTLV-II infection is present in indigenous populations in North and South America, while HTLV-I infection is predominantly in Africa, the Caribbean and Japan.

The most important human retroviruses in terms of disease are HIV (HIV-1 and HIV-2). These viruses cause human AIDS, and as described above they represent relatively recent movement of infection from African primates into humans.

Recently another retrovirus was reported to be associated with human prostate cancer (PC) and chronic fatigue syndrome (CFS), xenotropic murine leukemia virus-related virus (XMRV). XMRV was originally suggested to be a human retrovirus present in prostate cancers from patients with an inherited predisposition to PC. Subsequently XMRV also was reported to be detectable in tissues from CFS patients. However a number of follow-up studies did not confirm the presence of XMRV in either of these diseases. Subsequently XMRV was found to have arisen by activation and recombination of endogenous murine leukemia viruses during passage of a human PC tumor through immunocompromised (nude) mice. XMRV could replicate in the human PC tumor cells growing in the nude mouse, but it was not present in the original human tumor. The detection of XMRV sequences in human tumors or CFS tissues resulted from laboratory contaminations, coupled with the highly sensitive PCR-based detection techniques employed.

Several reports have suggested that a virus closely related to MMTV is present in human breast cancer or tissues from biliary cirrhosis patients. These reports also are controversial, since other investigators have not confirmed them.

Host restriction factors for retroviruses

Due to the potential deleterious effects of exogenous retroviruses and their endogenous counterparts (ERVs, see below), many species have evolved restriction systems that limit exogenous retrovirus infection or transposition by retrotransposons. The initial infection step can be blocked by expression of an endogenous (genetically transmitted) envelope protein that binds to the receptor, blocking infection by an incoming retrovirus (viral interference). Certain chicken and mouse strains express such envelope proteins that block incoming retroviral infection. There are also host restriction systems that block viral infection intracellularly. The first intracellular restriction identified was the Fv-1 system for MuLVs in mice. There are two alleles for *Fv-1*, *Fv-1ⁿ* and *Fv-1^b*; likewise, MuLVs can be classified as N-tropic or B-tropic. *Fv-1^{n/n}* mice (or cells derived from them) are permissive for replication by N-tropic but not B-tropic MuLVs, while B-tropic but not N-tropic MuLVs can replicate in *Fv-1^{b/b}* mice. Resistance is dominant, that is *Fv-1^{n/b}* mice are resistant to both N- and B-tropic MuLVs. Fv-1 restriction occurs at an early post-entry step in viral replication – between reverse transcription and integration of viral DNA. The Fv-1 protein appears to be distantly related to a retroviral gag protein and it may interfere with viral replication by interacting with or mimicking MuLV Gag protein.

Another early post-entry restriction system is the TRIM proteins – proteins containing a tripartite motif consisting of a RING domain, a B Box-2 and a coiled-coil domain. This restriction was first identified in studies of HIV-1 replication. Cells of old world primates (e.g. rhesus macaques) are poorly permissive for HIV-1 infection, and it was found that they express a species-specific restriction factor, TRIM5 α – a TRIM protein containing a C-terminal extension with a B30.2 domain. The B30.2 domain binds viral capsid protein; the species specificity of different TRIM5 α 's is determined by this binding. Rhesus TRIM5 α restricts HIV-1 replication at an early step, similar to the stage for FV-1 restriction. Restriction may result from TRIM5 α -mediated degradation of viral cores, through a ubiquitin ligase activity on the protein. Species-specific restriction by TRIM proteins affects more retroviruses than HIV-1. For instance human TRIM5 α restricts intracellular replication of N-tropic MuLV, and TRIM5 proteins from African green monkeys and cattle restrict HIV-1, HIV-2, SIV_{mac} and N-tropic MuLV. Like Fv-1, TRIM5 α restriction can be abrogated by high levels of viral Gag protein.

Another interesting retroviral restriction system is the APOBEC3 proteins. APOBEC proteins are cytidine deaminases that deaminate cytosine residues to uracils in DNA or RNA. If incorporated into retroviral particles, certain APOBEC proteins can induce cytidine deamination in the first strand of reverse transcribed DNA, leading to G $\rightarrow$ A mutations in the viral genome. This restriction was first discovered by studies of HIV-1 and its *vif* gene. In *vif*-negative HIV-1, one APOBEC protein (APOBEC3G) is incorporated into virions as particles are assembled. Upon infection into the next cell, cytidine deamination of viral DNA during reverse transcription leads to extensive G $\rightarrow$ A mutations and blockage of viral replication. APOBEC3G can also block the overall rate of viral DNA synthesis, in addition to inducing G $\rightarrow$ A mutations. The Vif protein counteracts this restriction by binding to APOBEC3G protein in the initially infected cell and triggering proteosomal degradation by recruitment of a ubiquitin ligase. Thus virus particles produced from a Vif-expressing infected cell are free of APOBEC3G. The APOBEC restriction also affects other viruses. For instance human APOBEC3G also restricts MuLV infection in human cells, and murine APOBEC3 restricts replication of HIV-1 in mouse cells. For some situations (e.g. murine APOBEC3 restriction of Moloney MuLV in mouse cells), restriction does not involve mutation of viral DNA. For MuLVs, a novel form of Gag protein (glycosylated Gag) counter-acts the effects of murine APOBEC3 in mice. It is interesting that multiple APOBEC genes are present in many species; for instance mice have one APOBEC3 gene, while humans have seven (APOBEC3A – H). One hypothesis is that this resulted from evolutionary selection for resistance to infection by retroviruses and other viruses, as well as retrotransposition of endogenous retroelements. *In vitro* assays indicate that human

APOBEC3A and -B reduce retrotransposition of IAP retroelements in human cells, and murine APOBEC3 reduces retrotransposition of MusD elements in mouse cells. Moreover, all primate APOBEC proteins restrict retrotransposition of ubiquitous non-LTR retroelements (e.g. LINE and ALU elements).

The restriction factor BST2/tetherin functions at a late step in viral replication – release of virus particles from the infected cell. BST2/tetherin was discovered by studies on HIV-1, where it was found to be the target of the viral protein Vpu. BST2/tetherin is a component of the innate immune system, and it is inducible by interferon. When Vpu negative HIV-1 is infected into cells, budded virus particles are retrained (tethered) to the cell surface by interactions with BST2/tetherin. Vpu expression results in proteosomal degradation of BST2/tetherin or its direction away from the cell surface so that virions can be released from the infected cell. Some other retroviruses utilize other viral proteins to counteract BST2/tetherin, including SIV and HIV-2 that use the Nef and Env proteins respectively.

The most recently identified host restriction factor is SAMHD1, identified through studies on HIV-1. SAMHD1 is a deoxynucleotide hydrolase that hydrolyzes dNTPs and reduces the intracellular pools of these DNA precursors. This protein is also a component of the innate immune system and inducible by interferon. SAMHD1 is expressed in various hematopoietic cells, and it restricts viral replication in non-dividing myeloid cells and T-cells, predominantly by reducing their dNTP levels. It does not restrict replication in dividing cells, where dNTP levels are higher. SAMHD1 is counteracted by the Vpx protein encoded by HIV-2 and SIVs; interestingly HIV-1 does not encode a Vpx or other proteins that counteract SAMHD1.

Endogenous retroviruses

Most eukaryotic organisms carry retroviral DNA in their genomes as stably inherited elements. These elements are referred to as endogenous retroviruses (ERVs) and they represent retroviral infection of germ cells during evolution of a species. Once a germ cell is infected by a retrovirus, all progeny will inherit the proviral DNA. The ‘endogenization’ of retroviruses has occurred throughout evolution, with some ERVs entering the genomes relatively early during speciation (e.g. entry of some human ERVs [HERVs] in common ancestors to humans and great apes) while others have entered the germ lines relatively recently (e.g. entry of other HERVs after separation of humans from chimpanzees). Indeed, endogenization of retroviruses is presently occurring in some species (e.g. at high levels in the koala). In addition to the ERVs, there are also related genetic elements that resemble retroviruses except they lack coding sequences for an env protein. These elements, LTR retrotransposons, assemble particles and re-insert reverse transcribed DNA into the genome without an extracellular phase (retrotransposition). Over evolutionary time scales, multiple copies of endogenous retroviruses or LTR retrotransposons have accumulated in the genomes of most eukaryotes; once inserted, there is no molecular mechanism for removal. Indeed, it is estimated that approximately 8% of the human genome is made up of ERVs and LTR retrotransposons. This includes ‘solo LTRs’ that result from excision of the ERV coding sequences by homologous recombination between the two LTRs.

Insertion of retroviral proviruses into the host genome can be detrimental to the host organism if the provirus insertion disrupts a gene or leads to activation of a proto-oncogene. Thus there has been genetic selection against replication-competent ERVs that could continually reinfect the host; most ERV genomes carry mutations and/or deletions. However, for some species there are ERV genomes that can encode full-length proteins, and some species carry replication-competent ERV proviruses (e.g. mice). There are no replication-competent HERVs in the human genome.

Endogenous retroviruses have several biological effects on their host species. In some cases, endogenous retroviruses can prevent infection by related exogenous retroviruses. A common mechanism is expression by an ERV envelope protein (see above). This has been observed for restriction of alpharetroviruses in chickens. For instance C/A chickens express an endogenous envelope protein for subgroup A retroviruses; these cells are resistant to infection by exogenous subgroup A viruses that use the same receptor. In mice, strains carrying the *Fv-4* gene are expressing the Env protein of an endogenous MuLV that renders them resistant to infection. ERVs can also interact genetically with related exogenous retroviruses when they infect the cell. For instance, when exogenous MuLVs infect mice, recombinant MuLVs containing a new *env* gene appear, MCF recombinants; MCFs result from recombination with an endogenous MuLV. MCF recombinants have an expanded host range in that they can infect cells of both mouse and non-mouse origin (polytropic); this reflects the host range of the Env protein encoded by the endogenous MuLV donors (polytropic or modified polytropic ERVs). MCF recombinants have been implicated in the development of MuLV-induced leukemia. It is noteworthy that the polytropic and modified polytropic ERV proviruses are themselves replication-defective, even though they can donate a functional *env* gene by recombination. Finally in some cases, ERV's have affected expression of a cellular gene by insertion into it. For instance, the *dilute* coat color mutation in mice results from insertion of an MuLV-type ERV.

The most dramatic biological effects of ERVs is the role of ERV envelope proteins in normal embryonic development. During early human development, extra-fetal embryonic cells fuse to make syncytial trophoblasts. The fusion is mediated by the proteins syncytin-1 and 2. Cloning and sequencing of these genes revealed that they are actually endogenous retroviral envelope proteins encoded by HERV-W class proviruses. It is striking that in mice and sheep ERV envelope proteins also have been co-opted by the host to mediate syncytial trophoblast fusion. However different ERVs have been employed for each of these different species. Thus in at least three independent cases the host has taken advantage of the membrane fusing capacity of endogenous retroviral envelope proteins and used them to optimize fusion of host cells during embryogenesis. Presumably a less efficient mechanism independent of ERV Env proteins is the default mechanism for syncytial trophoblast fusion in all mammals, but enlisting fusion by ERV env proteins facilitates this process.

Retroviral vectors

Retroviruses have been developed as gene expression vectors. Retroviral vectors have been used in the laboratory to obtain efficient expression of genes in cells, and also to knock down of expression of specific genes by introduction of interfering RNAs (e.g. small hairpin or shRNAs). In addition, they are being developed as clinical gene therapy vectors where introduction of genes into patients may be used to treat different diseases. Retroviral vectors take advantage of several aspects of the retroviral lifecycle, most notably that integration of proviral DNA into the host genome is a step in the replication process. As a result, these vectors offer the prospects of prolonged high level expression of the target gene in the vectored cell. Retroviral vectors based on gammaretroviruses (e.g. MuLVs), alpharetroviruses (e.g. spleen necrosis virus) and lentiviruses (e.g. HIV-1) have been developed. A typical retroviral vector DNA plasmid is generated by inserting the target gene into a retroviral provirus by molecular cloning. While some retroviral sequences may be eliminated during the cloning (e.g. those encoding the viral structural proteins), the essential retroviral sequences maintained in the vector plasmid are the LTRs and the RNA packaging signal (Ψ). This vector DNA is then co-transfected into cells along with helper expression plasmids for the viral structural proteins; the mRNAs from the latter plasmids lack the Ψ sequences so they themselves cannot be incorporated into retroviral particles. Alternatively, the vector DNA may be transfected into a retroviral vector 'packaging cell' that permanently expresses viral structural proteins from Ψ -negative mRNAs. In either case, the transfected cells will produce retroviral particles that contain only RNAs encoded by the vector plasmid ('helper-free'). The resulting vector particles will infect susceptible cells, reverse transcribe the vector DNA and integrate it into the chromosomal DNA where it can be stably expressed. However, since the retroviral vectors do not express the viral structural proteins, they will not assemble infectious particles that spread the vector infection. Introduction of genes into cells by way of retroviral vector infection is termed transduction.

Variations of the basic retroviral vector design have been developed that address practical and theoretical concerns. Some retroviral vectors rely on the viral LTR as the promoter for the target gene, in which case the transcriptional specificity is dictated by that of the viral LTR. To increase expression in other kinds of cells, substitutions by LTRs with different transcriptional specificities has been employed. Alternatively, an internal cellular or viral promoter is inserted within the vector to drive target gene expression independent of the LTR. Expression of the target gene protein (or expression of two target genes from the same promoter) can be enhanced by insertion of an internal ribosome entry site (IRES) upstream of the target gene coding sequences. Another challenge has been that integrated retroviral vector DNAs tend to undergo transcriptional silencing over time (e.g. through DNA methylation). Approaches to this problem have been to include cellular transcriptional insulator elements in the vectors, or to use lentiviral vectors where there may be less silencing. The original retroviral vectors employed retroviral envelope proteins on the vector particles for cell entry. Thus the host and tissue specificities of the vectors were determined by the Env proteins; moreover, retroviral envelope proteins are dissociated from viral particles relatively easily during purification or concentration. It is possible to use the heterologous G-protein from vesicular stomatitis virus (VSV, a rhabdovirus) to form pseudotypes in which the vector particles contain retroviral Gag and Pol proteins, but with VSV-G protein in the envelope. These pseudotypes have the advantages that VSV-G has a broad host range, and it is tightly anchored by way of a glyco-phosphatidyl inositol (GPI) linkage into the lipid bilayer of the viral envelope. As a result infectious vector particles can be efficiently concentrated by ultracentrifugation. In contrast, ultracentrifugation strips many retroviral Env proteins from the particles.

Other aspects of retroviral vector design address safety concerns. One concern is that recombination between retroviral vector and helper plasmid DNAs or RNAs could result in recovery of replication-competent retroviruses (RCRs). To reduce the likelihood of RCR formation, modern vector systems generally employ at least three different plasmids to express the vector genome and viral structural proteins. Thus formation of an RCR would require three or more recombination events. In practice, in clinical experiments all retroviral vector stocks are tested for the absence of RCRs by sensitive biological assays prior to use. The second safety concern is that introduction of retroviral vectors into patients could lead to induction of cancers by insertional activation of proto-oncogenes (see above). Recent clinical trials have indicated that this is a real concern in at least one setting (see below). One approach is self-inactivating (SIN) vectors. In these vectors, the vector plasmid has a complete upstream LTR, but deletion of the promoter and enhancer sequences in the U3 region of downstream LTR; target gene expression is driven by an internal heterologous promoter (Fig 5). In the transfected vector-producing cell, the vector genome transcription is driven by the wild-type upstream LTR. However, in the transduced cell, reverse transcription will result in the integrated vector provirus containing U3-deleted (and inactive) LTRs in both upstream and downstream positions. The transgene will be expressed from the internal promoter, but the likelihood of activation of adjacent proto-oncogenes will be reduced since there are no active LTRs present.

Retroviral vectors have been tested in human clinical trials for several medical applications. One application is to use retroviral vectors to restore genes to individuals with single-gene defects such as hemophilia, adenosine deaminase deficiency (SCID), and common gamma chain deficiency (X-linked SCID). In some cases target cells (e.g. hematopoietic progenitors) are isolated from the patient and subjected to vector transduction *ex vivo*. Alternatively, infectious vectors are infected directly into target tissues. In some cases, positive clinical results have been obtained, most notably correction of the severe combined immunodeficiencies (SCIDs) associated with inherited adenosine deaminase and common gamma chain deficiency. However, in the treated X-linked SCID patients (treated with a first-generation MuLV-based vector), a significant percentage developed T-cell leukemia resulting from insertional activation of a proto-oncogene (LMO2). While this had been a theoretical possibility, the actual occurrence of leukemias in at least one clinical setting demonstrated the importance of this concern. In another more recent trial, gene therapy

Figure 5 Retroviral vectors. Components to generate a typical retroviral vector are shown at the top. They include a plasmid encoding the retroviral vector as well as helper plasmids encoding the viral structural proteins from mRNAs that cannot be packaged since they lack the RNA packaging signal (Ψ). Vector particles are generated by transient co-transfection of vector and helper plasmids, or by transfection of vector plasmid into cells that stably express the helper plasmids (packaging cells). A self-inactivating (SIN) vector is shown at the bottom, in which the U3 promoter/enhancer sequences are deleted from the downstream LTR of the vector plasmid. Transient transfection into a producer cell yields vector particles with deleted U3 regions in their RNA; after infection into a target cell (transduced cell), the resulting provirus will contain deletions in both LTRs. Transcription of the target gene will be driven by an internal promoter.

of a beta-thalassemia patient with a lentiviral vector expressing beta-globin resulted in clinical benefit. In this patient there is a major clone of modified cells, which shows over-expression of the HMGA2 gene and protein. HMGA2 has been associated with malignancies in some cancers, but so far this patient has shown no evidence of malignancy.

Another clinical application of retroviral vectors has been to use them to express antigens or immunostimulatory molecules in cancer cells with the goal of stimulating a host immune response to the tumors – cancer vaccines.

Further Reading

The definitive reference book for retroviruses is Coffin et al. (1997). It contains comprehensive extensively cited chapters for most topics. For more recent updates, chapters on retroviruses in Fields Virology (Knipe & Howley, 2013) are valuable.

Glossary

Bacteroids Nitrogen-fixing rhizobia in the central zone of a legume nodule.

Classical rhizobia Bacteria of the genera *Rhizobium*, *Bradyrhizobium*, *Sinorhizobium* (*Ensifer*), *Mesorhizobium*, and *Azorhizobium*.

Infection thread The tubular structure through which rhizobia invade the developing legume nodule.

Legumes Members of the Leguminosae, the third largest family of flowering plants, traditionally distinguished by their fruit morphology (seed pods) and divided into the subfamilies Caesalpinioideae, Mimosoideae, and Papilionoideae.

Nitrogen fixation The reduction of molecular nitrogen (N_2) to ammonia (NH_3).

Nitrogenase The enzyme system that catalyzes the reduction of N_2 to ammonia within prokaryotic organisms.

Nodule The organ on legume roots, and sometimes stems, induced and invaded by rhizobia.

Nod factor A lipochitooligosaccharide molecule that incites nodule formation and root hair curling on susceptible legumes.

Plasmid Bacterial DNA molecules that are smaller than the chromosome(s), ranging in size from 1000 to 2,000,000 nucleotides, and generally dispensable for basal bacterial growth.

Symbiont One of the partner organisms in a symbiosis.

Symbiosis The intimate association of two organisms of different species, classically divided into three categories: mutualism (both organisms benefit), commensalism (one organism benefits), and parasitism (one organism benefits and the other is harmed).

Defining Statement

Rhizobia are diverse Gram-negative members of the Proteobacteria that fix nitrogen inside root and stem nodules, which they incite on leguminous plants. All are facultative symbionts, and as a group they are successful soil bacteria. They have diverse metabolic capabilities, but most often couple versatile heterotrophy with aerobic, microaerobic, and anaerobic respiration. As rhizobia are metabolically versatile, they are widely used as plant growth promoters of multiple legumes and cereals. Rhizobia utilizes C4 acids in preference to sugars and the sugar utilization is reserved as long as C4 acids are present. This is apparent as a diauxie when rhizobia are grown in the presence of a sugar and a C4 acid together. Several reports have shown succinate to repress the enzymes required in transport and utilization of sugars, sugar alcohols, hydrocarbons, etc. This mechanism is termed as Succinate Mediated Catabolite Repression (SMCR).

Nitrogen Fixation in Legumes and its Global Significance

Nitrogen fixation is the reduction of atmospheric nitrogen (N_2) to ammonia (NH_3). The nitrogen atoms in N_2 are triply bonded to each other, and this molecule is very inert chemically. Abiotic chemical conversions of N_2 either cannot occur (are disfavored energetically) or occur at exceedingly low rates under normal ambient conditions. Only rare intense bursts of energy such as lightning provide sufficient activation energy and highly reactive molecules that allow formation of other compounds from N_2 . Even with suitable catalysts, high temperatures and pressures are required to form ammonia from N_2 (as in the industrial Haber–Bosch process first commercialized about a century ago). In this context, biological nitrogen fixation is truly remarkable. It provides almost the only natural entry into living systems from the huge reservoir of nitrogen in the atmosphere.

Nitrogen fixation occurs only in prokaryotes. The minority of prokaryotes capable of it are termed diazotrophs, and rhizobia are the best-known symbiotic diazotrophs. In the rhizobia–legume symbioses, this reaction occurs within nodules, organs that develop only in the presence of rhizobia (Fig. 1). Nodules may be determinate or indeterminate. Determinate nodules are found on certain tribes of tropical legumes like soybean, common bean, and on some temperate legumes such as Lotus. As determinate nodules lose meristematic activity shortly after initiation, growth is due to cell expansion resulting in mature spherical shaped nodules.

Indeterminate nodules are found in the majority of legumes from all three sub-families and are termed “indeterminate” because they maintain an active apical meristem which produces new cells for growth over the life of the nodule. This results in formation of cylindrically shaped nodule, which may be extensively branched. Indeterminate nodules manifest zones demarcating different stages of development/symbiosis, as they are actively growing. On some water-tolerant legumes, nodules develop on stems, but much more commonly they appear on roots. Other important symbiotic diazotrophs include *Frankia*, an actinomycete genus whose species incite root nodules on at least 23 genera of plants in eight families of the rosoid I clade of the dicotyledonous angiosperms (Fig. 2), and cyanobacteria, which form nitrogen-fixing symbioses with lower plants and fungi (in lichens). Some animals, such as those which feed on wood, also enter into symbiosis with diazotrophs.

The relationship between rhizobia and legumes is the best-known, best-understood mutualistic symbiosis between a prokaryote and a eukaryote. It is clear that the legumes benefit as they are allowed vigorous growth in nitrogen-deficient soil. This symbiosis is undoubtedly a major factor in the great success of legumes as a plant family. In contrast, some scientists have questioned whether the bacteria benefit or, at least, how they benefit. Nevertheless, the increased soil population of specific rhizobia after the cultivation of a compatible legume crop seems an obvious indicator that the symbiosis provides a reproductive benefit that should promote evolution of the species.

After photosynthesis, N fixation is considered as the second most important process influencing primary productivity and is the basis of all life on earth. Annually, approximately 2.5×10^{11} kg NH_3 is fixed from the atmosphere through BNF (by legumes and cyanobacteria) and approximately 8×10^{10} kg NH_3 are manufactured by ammonia industry. Further, lightning may also contribute approximately 1×10^{10} kg NH_3 /year worldwide. Currently, approximately 2 tonnes of industrially fixed N is needed as fertilizer for crop production to equal the effects of 1 tonne of N biologically fixed by legume crops. Therefore, biologically fixed N influences the global nitrogen cycle substantially less than industrially fixed N. In order to keep up with the demands of food, world population has been increasingly relying on nitrogen fertilizers. World demand for total fertilizer nutrients grew at

Fig. 2 Gross outlines of legume classification for the purposes of this article. At the bottom left the concentric ovals indicate first that the legumes belong to the Rosid I clade of the Rosids. The Rosids in turn are a clade within the Eudicots ('dicots') of the angiosperms, the flowering plants. Genus *Parasponia* is in Rosid I outside of the legume family. The branchings on the right side are meant to give a rough sense of the divergence among the various groups of legumes specifically mentioned in the text. Four genera (in italics), three tribes, and the three subfamilies (in capital letters) are indicated. © 2008 Dale Noel. Published by Elsevier Inc. All rights reserved.

2% per annum between 2011 and 2015; the demand for N is forecast to grow annually by 1.7% globally and by 2.6% in south Asia. Globally, BNF in natural terrestrial ecosystems contributes about 107 Tg of N (1 Tg=1 million tonnes) while marine N fixation contributes 121 Tg of N each year. BNF induced via agricultural crop cultivation adds 33 Tg per year. Symbiotic BNF by *Rhizobium* associated with seed legumes adds around 10 Tg, leguminous cover crops add about 12 Tg/yr, non *Rhizobium* N fixing species 4 Tg/yr, cyanobacteria in wet rice fields 4–6 Tg and endophytic N fixing organisms in sugarcane- 1–3 Tg. This makes the total terrestrial nitrogen fixation around 140 Tg N/year. It is estimated that cultivation induced BNF may have risen to 40 Tg/yr due to increase in soybean and meat production. Soybean is the dominant crop legume representing 50% of the global crop legume and fixes 16.4 Tg N annually, representing 77% of the N fixed by the crop legumes. Haber Bosch process can fix about 3 times as much N relative to cultivation induced BNF. About 100 Tg N per year of ammonia produced via Haber Bosch process in 1995, about 86% was used to make fertilizers. The industrial fixation of N is increasing each year with the setting up of more plants and it reached to 121 Tg by 2006 with the worldwide manufacture of N fertilizer at 105 Tg. Predicament with man-made fertilizers is that they are used in excess to achieve maximum crop yields which leaches into water sources, creating problems in inland aquatic ecosystems and sometimes massive plumes of eutrophic pollution. Hence, a transition toward agricultural diversification using legume-based crop rotations may be highly desirable, as it may limit the intensity of ammoniacal fertilization with the input of less reactive organic N.

Rhizobia and legumes are important in agriculture and related commerce. Certain legumes are very important agricultural crops, as forage, animal feedstock, food directly consumed by humans, and commodities processed into a large number of end products. Legumes are estimated to supply about 20% of worldwide food protein. Soils deficient in the appropriate rhizobia can be inoculated with that specific rhizobia to enhance nodulation and the overall yield of a legume crop. The Global Agricultural Inoculants Market is perched to grow at a CAGR of around 9.9% over the next decade to reach approximately \$ 710.16 million by 2025. Sometimes, an objective of planting legumes is to improve the N content of the soil for the benefit of other crops. In this respect, it is important to realize that growing legume plants do not leak appreciable amounts of fixed N into the soil. Soil N is materially improved by cultivated legumes only when the legume plants and seeds are plowed into the soil, rather than harvested or eaten directly by livestock.

Phylogeny and Taxonomy

Taxonomy and phylogeny of bacteria is a dynamic topic; any current classification scheme is subject to future revision. Most of the rhizobial species in the alpha-proteobacteria class of phylum proteobacteria in Rhizobiaceae family are in either the *Rhizobium*, *Mesorhizobium*, *Ensifer*, or *Bradyrhizobium* genera. However, recent research has exposed many other rhizobial species in addition to already existing ones which may have occurred through lateral gene transfer of symbiotic genes. Genera of rhizobia are currently divided into the groups shown in Table 1.

The term 'rhizobia' defines a group of bacteria based on one complex property, the inciting of legume nodules inside which nitrogen is fixed. The rationale for considering these bacteria as a group is based on the great interest in and the importance of this property, rather than believing that they all belong to one monophyletic evolutionary group. On the contrary, rhizobia are polyphyletic and much more diverse than what had been supposed even a decade ago. The history of the ongoing revisions in their classification, and the accompanying consternation among nontaxonomists, illustrates the overall revolution in bacterial taxonomy within the past three decades. However, the realization that rhizobia did not belong collectively to a single, simple taxon had emerged, though gradually, much earlier.

Table 1 Classification of rhizobia

The early history of studying root nodules climaxed in 1888 when Beijerinck became the first to isolate a bacterium capable of nodulating a legume, naming the isolate *Bacillus radicola*. Frank in 1889 decided that all bacteria isolated from legume nodules would be assigned the name *Rhizobium leguminosarum*. The type strain for the genus and species was isolated from pea nodules. Subsequently, after E.B. Fred and colleagues in 1932 proposed the cross-inoculation concept, the taxonomy of the genus *Rhizobium* was, for many years, based on the host specificity of nodulation. Cross inoculation is a test for whether an isolate from one plant species incites nodules on another plant species. The taxonomic concept was that the rhizobia fell into groups defined according to the plants nodulated by each group. This concept was very useful in agriculture, but, gradually, it was appreciated that this classification scheme and the cross-inoculation concept often were very poor predictors of the true relatedness and diversity of these bacteria. The first departure from this taxonomy was based on growth rate in culture ('fast growers' vs. 'slow growers'), with the slow growers being assigned to a new genus, *Bradyrhizobium*.

Since the 1980s, rhizobial taxonomy has been based on nucleotide sequences, mainly of the DNA encoding ribosomal RNA, mirroring the efforts of bacteriologists in general to create a taxonomy reflective of true phylogenetic relatedness. Recently, the availability of total genomic sequences has supported the basic genetic relatedness deduced in this way.

By 2006, 48 species of rhizobia had been classified among six genera whose names include the root word 'rhizobium'. By 2016, this number increased to 125 species of rhizobia classified among fifteen genera (Table 1). In addition, at least 11 Proteobacterial species outside these more 'classical' genera are capable of eliciting nitrogen-fixing nodules on legumes. These latter species are found in nine genera in the alpha division of the Proteobacteria and two genera in the beta division of the Proteobacteria (Table 1). Discovery of legume-nodulating bacteria among the beta Proteobacteria is the most recent and the most dramatic indication of the breadth of distribution of this property among diverse bacteria. The current taxonomy predicts what physiological characterizations have borne out: aside from entering into symbiosis with legumes, the different groups of rhizobia exhibit great diversity in other properties.

The dynamic nature of current bacterial taxonomy is illustrated by the case of *Sinorhizobium meliloti*. This species has a long history of study and was one of the first species to be included within 'Rhizobium' by the cross-inoculation concept. About two decades ago, it became apparent that this species did not belong to a genus whose type species was *R. leguminosarum*. Because of its close genetic relationship with the type species of the genus *Sinorhizobium*, *S. fredii*, this well-known bacterium was renamed *S. meliloti*. Very recently, it has been discovered that this genus should include bacteria previously assigned to the genus *Ensifer*. Members of the genus *Sinorhizobium* have undergone another name change to *Ensifer*, as *Ensifer* as a genus name preceded the naming of *Sinorhizobium*.

It is likely that some of the organisms now classified as *Bradyrhizobium* and *Rhizobium* will eventually be reclassified under different genus names. Both are very diverse genera according to the current norm in bacterial classification. They include rhizobia more closely related to bacteria in different genera than to other rhizobia within the genus to which they are presently assigned. Likewise, certain species currently assigned to other genera probably should be moved to *Rhizobium* or *Bradyrhizobium*, if progress toward a rational taxonomy is to be continued. A controversial example, which has implications for certain species grouped within the venerable genus *Agrobacterium* and some currently assigned to *Rhizobium*, involves the single species of the genus currently named *Allorhizobium*. In Table 1 this latter genus name is in parentheses because this species and possibly several closely related *Rhizobium* species are likely to undergo reclassification.

Rhizobial Host Ranges

Legumes are a very successful family of plants, known in botany as the Fabaceae or Leguminosae. In traditional taxonomy it is the third largest family within the angiosperms (flowering plants), with more than 700 genera and 20,000 species. This family is divided into three subfamilies: Caesalpinioideae, Mimosoideae, and Papilionoideae (Fig. 2). About 20% of the known legume species have been studied to determine whether they nodulate. All three subfamilies have members that form nitrogen-fixing nodules, but most of the well-known symbioses are in the Papilionoideae. It should be noted that there are legumes that, despite extensive

examination in some cases, have never been documented as nodulating. In surveys among the Caesalpinioideae, 10% of the genera were observed to nodulate. Nodulation is much more common among Mimosoideae (about 80% of the genera surveyed) and Papilionoideae (about 90% of the genera surveyed).

Historically, great attention has been placed on the host range of the rhizobia, and any description of a species generally has included its known host range. Some rhizobia have very narrow host ranges, composed of only one or a few closely related legume species, whereas others have much broader host ranges. One *Sinorhizobium* (*Ensifer*) strain, NGR234, can nodulate legumes belonging to at least 112 genera that include representatives of all three subfamilies.

Host range is a complex issue with many caveats. Obviously any statement regarding host range is limited by the number of potential hosts that have been tested. In addition, it should be strictly qualified according to the symbiotic parameters that have been observed. A strain may incite nodules, but may not provide nitrogen fixation. Hence, the host range of nitrogen fixation ('effective' symbiosis) is narrower than the host range of nodulation.

Within a rhizobial species, different strains can have clearly different host ranges. For instance, some strains of *R. leguminosarum* nodulate pea ('biovar' *viciae*), whereas others nodulate clover (*bv. trifolii*) or bean (*bv. phaseoli*). These bacteria are all assigned to the same species because of the close homologies of their chromosomes, whereas, in this species, host range is specified by genes on plasmids. A given strain can be converted from one host range to another by replacing one plasmid with another. This was one type of observation that persuaded geneticists that cross inoculation was not a proper way to define species. Adding further complication is that these genetically defined host ranges overlap to differing degrees. Certain *bv. viciae* strains elicit some degree of nodulation on beans, and the quality of the nodulation can depend on the variety or race of the bean plant. The converse is also true. There are variant individuals within a host species that resist nodulation by a rhizobial strain that does well on most other races, cultivars, and varieties of that host. This type of incompatibility can be strain-dependent and sometimes has been traced to presence or absence of specific genes in the rhizobial strain. However, rhizobial host range can be modified as transfer of a plasmid carrying *Rhizobium meliloti* host genes to *R. leguminosarum bv. viciae* enabled *R. leguminosarum bv. viciae* to infect and nodulate alfalfa, the normal host of *R. meliloti* but stringently inhibited infection and nodulation in normal vetch, its normal host.

Given that rhizobial taxonomy is now based on divergence of ubiquitous chromosomal genes, such as those for ribosomal RNA, and that the genetics of symbiotic host specificity allows variation of host range among the strains of one species, one might ask whether there are any correlations between rhizobial taxonomic groups (species and genera) and host taxonomic groups. Table 1 implies that there are such correlations, and, indeed there are many inconclusive overall trends of this sort. For example, among legumes in the genus *Mimosa* (in the subfamily Mimosoideae), a majority of the reported nodule isolates belong to the beta Proteobacteria. Nevertheless, some of the beta Proteobacterial rhizobia that do well on *Mimosa* were isolated first from legumes in the subfamily Papilionoideae. Moreover, Bradyrhizobia also are commonly isolated from *Mimosa*. Therefore, this correlation is not a tight one. Another generalization is that, among highly diverged 'temperate' legume tribes within the Papilionoideae (including Trifolieae and Fabeae among others), 'fast-growing' rhizobia of the alpha Proteobacteria predominate. However, such rhizobia are also found as symbionts elsewhere among the legume family. Particular species have been observed to deviate from the general trend shown by the other species within a genus or tribe of rhizobia or legumes. For example, among isolates of *Phaseolus vulgaris* (common bean) nodules, fast growers predominate, but for other genera of tribe Phaseoleae and even other species of the genus *Phaseolus*, Bradyrhizobia usually predominate.

A related evolutionary question is whether symbiotic organisms, particularly in mutualisms, evolve toward high specificity for each other as a way to maximize the efficiency of interaction. There is no convincing evidence to support this possibility as the overall tendency among the rhizobia. However, there are instances in which the host genus and the bacterial species are mainly restricted to each other. One well-documented example is the legume genus *Trifolium* (clover) and *R. leguminosarum bv. trifolii*. Within this host-bacterial group, there is further restriction in that some of the bacterial strains nodulate and fix nitrogen only on certain *Trifolium* species. Does such specificity provide selective advantage, or is it an evolutionary accident? Judging by whether specialists give better nitrogen fixation than generalists, the overall evidence is mixed. Although the most promiscuous rhizobial strain, NGR234, is a poor symbiont on many of its hosts, there are many instances in which, for example, a *Bradyrhizobium* strain is very efficient on several disparate hosts.

Parasponia in the Ulmaceae (elm) family is the only known nonlegume genus that is nodulated by bacteria that also nodulate legumes. Strains within several different groups of rhizobia, including the aforementioned *Sinorhizobium sp.* strain NGR234, have been found to nodulate this host, but its most effective known symbioses are with certain bacteria currently classified within the genus *Bradyrhizobium*. It is striking how often members of this latter genus, or closely related bacteria, are found as the dominant symbionts of legumes in the Caesalpinioideae and Mimosoideae, as well as in the diverse taxa of the Papilionoideae.

Development of the Symbiosis

As a general rule, legumes develop nodules in nature only in the presence of the appropriate rhizobia. There is now a basic understanding at the cellular and molecular levels regarding how nodules develop. The paradigm described in the following sections has been established by studies with a relatively few legume-rhizobia combinations, those involving certain agronomically important legumes and some closely related model legumes. All are from the subfamily Papilionoideae and fall into just four of the many diverse tribes within this subfamily. They include soybeans, common beans, and cowpea in the tropical tribe Phaseoleae and

alfalfa, clover, and peas in the temperate tribes Trifolieae and Fabeae (Fig. 2). The model organisms are *Medicago truncatula* in the same genus as alfalfa in the Trifolieae and *Lotus japonicus* within a separately-diverged tribe, the Loteae. These hosts exhibit what is sometimes called the root hair-infection type of nodule development, which is observed in the majority of legume–rhizobia symbioses. After presenting a summary of this type of development, deviations shall be discussed.

Development Involving Nod Factors and Root Hair Infection

Formation of the Nodule Primordium

Legume roots and germinating seedlings exude flavonoid compounds that induce specific rhizobia in the vicinity to produce and secrete a glycolipid, the Nod factor (Fig. 3). This rhizobial compound then elicits two important responses in the plant: the curling of root hairs as they develop and the triggering of cell division in root cortex cells to form the nodule primordium. The primordium further generates cells that differentiate to become the nodule. In the Phaseoleae, this cell division initiates in the outer cortex. In the Trifolieae and Fabeae, it begins within the inner cortex near the root pericycle. In the latter cases, the cell division generates a permanent meristem that leads to elongated indeterminate nodules, whereas the former leads to transient meristematic activity and determinate nodules (Fig. 1). *Lotus* nodule development has elements of these two extremes; the primordium develops deeply in the cortex but the meristem is transient and determinate nodules result.

Recent progress with the plant genetics and cell biology of nodule formation has provided insight into the plant response to Nod factors. The earliest responses that have been documented are a rapid calcium flux into the root hair cell and the resulting fluxes of other ions that cause plasma membrane depolarization. About 10–15 min later, dramatic oscillations in cytosolic calcium, called calcium spiking, have been ordered into a developmental pathway according to the relative time at which the proteins specified by the genes appear to act. The first genes in the pathway encode presumptive Nod-factor receptors whose amino acid sequences align with those of a family of proteins that bind molecules resembling the oligochitin backbone of the Nod factors. Mutations in these genes block all responses to Nod factors including root hair curling. Mutations in some of the other genes affect actions downstream in the pathway; they block the calcium spiking completely or partially. Further downstream in the pathway is a nuclear calcium/calmodulin-dependent kinase. Null mutants in this protein block further progress to nodule primordium. More interesting are mutants in which this protein is constitutively active and that form nodule primordia in the absence of Nod factor. Further downstream in the pathway is a cytokinin receptor with cytokinin-dependent kinase activity. Mutants in which this protein is constitutively active also form nodule primordia in the absence of Nod factor. Hence, plant genetics suggests that formation of nodule primordia is a series of events involving at first mainly calcium fluxes as secondary signals to activate downstream protein phosphorylation events and, later, activation of further protein phosphorylation by the important plant hormone cytokinin. How this pathway connects with regulation of transcription factors and the proteins that carry out visible organogenesis remains to be elucidated. These latter proteins include nodulins, proteins that are highly upregulated in nodules. A large number of such proteins have been identified.

Fig. 3 *S. meliloti* NF structure and Nod protein function. Each Nod protein is encoded by an equivalently named *nod* gene. NodA, NodB and NodC are common to all rhizobia. The remaining Nod proteins are responsible for the modifications of NF that confer activity on selected legume species. NodF and NodE are required for the synthesis of the unsaturated fatty acid whereas NodL is required for the attachment of an O-acetyl group at the non reducing end.

Infection

Coincident with this organogenesis is the second major developmental program, the infection process whereby the rhizobia enter the developing nodule. Nod factor is believed to potentiate this second process by causing the development of curled, and often otherwise deformed, root hairs. Generally, the infection starts from a tightly curled portion of the root hair or where a curled root hair is folded against the main body of the root hair cell. From a colony of rhizobia seemingly trapped within the folds of the root hair, there develops a narrow tubular structure known as the infection thread. At the core of the infection thread are rhizobial cells in linear files. Surrounding the bacterial colony is a tubular plant wall. This wall is itself surrounded by a tubular plant plasma membrane, which at all times and locations separates the bacteria from the plant cytoplasm through which the infection thread develops. At the growing tip of the infection thread, one end of the leading bacterium is in close proximity to the plant membrane. Everywhere else the bacterial colony is surrounded by the plant wall. Fig. 4 shows infection thread development in *M. truncatula* root hairs.

Growth of the infection thread is thought to derive basically from two influencing factors: bacterial growth and growth of the surrounding plant membrane. According to this idea, bacterial cell fission and enlargement provide the basic driving force for the process. Observations indicate that the bacteria divide only near the growing tip of the infection thread, whereas the rest of the bacterial colony is enmeshed in a matrix of polymers deriving from both the plant and the bacteria. This enmeshed portion of the colony provides a solid anchor for the push from the dividing bacterial cells. As the bacterial colony pushes into a plant cell, the plant plasma membrane invaginates to surround the bacteria. The narrow tubular nature of its subsequent growth hypothetically arises from membrane vesicles in the plant cytosol fusing only at the tip of the infection thread membrane. Not only membrane lipids and proteins, but also the material and enzyme machinery for extending the thread wall inside the growing membrane are delivered by these vesicles. The shape and dimensions achieved in synthesizing this tubular wall are the third, and the permanent, influencing factor on the size and orientation of the infection thread.

Formation of the Bacteroid Zone and Nodule Maturation

The infection thread branches and spreads the infection in all three dimensions. As the infection thread penetrates deeper into the layers of cells in the developing nodule, the last stage of infection begins: bacterial release into certain plant cells that become filled with rhizobia. During this endocytosis at the unwall tips of infection threads (or from enlarged unwall areas known as infection droplets) the bacteria get surrounded with plasma membrane from the plant. The bacteria differentiate into nitrogen-fixing cells known as bacteroids, and the surrounding plant membrane becomes the specialized peribacteroid membrane. The

Fig. 4 Cytoarchitecture associated with IT development in *M. truncatula* root hairs. Three successive stages of IT growth in a root hair of the supernodulating *M. truncatula* mutant sunn expressing the 35S-GFP-HDEL transgene (4 d postinoculation). Bright-field images are shown on the left (A, D, and G). The corresponding confocal images (z axis projections of serial optical sections) showing the cCFP fluorescence of the rhizobia (magenta) are presented in B, E, and H, and combined with the ERtargeted GFP-HDEL (green) in C, F, and I. Cell wall autofluorescence in the confocal images is in red. A to C, At this early stage of IT development, there are only a very few bacteria in the thread, and several gaps are clearly visible within the file (B). The broad ER-rich cytoplasmic bridge (A and C, arrowheads) connecting the nucleus (n) with the elongating IT (arrow) is characteristic of actively growing ITs (C). Note that the IT tip is embedded in the dense, ER-rich cytoplasm and therefore difficult to visualize in the bright-field image. D to F, 3.5 h later, the IT has progressed within the root hair (D), and the rhizobia multiplied within the thread (E). Gaps are again visible within the single file of bacteria. The more mature section of the IT is surrounded by a layer of cytoplasm, whereas the newly synthesized region is embedded in the cytoplasmic bridge (F, arrowhead). Note that the root hair nucleus has moved down the shaft of the root hair and is no longer visible in the image frame. G to I, 20 h later, the IT has grown further down the hair toward the base of the cell. The bright-field image (G) shows the clear outline and uneven surface of the typical mature IT, and the confocal image (I) reveals that this fully differentiated IT is still surrounded by a thin layer of ER-labeled cytoplasm. Thicker stretches of the colonizing bacterial file (H) suggest that there is a doubling in certain regions (H) and, even at this late stage, bacteria-free gaps are still present along the file. Bars=10 mm. Copyright © 2008 American Society of Plant Biologists.

resulting cellular units consisting of bacteroids and the surrounding peribacteroid membranes are often termed symbiosomes. Depending on the host, a symbiosome contains one or several bacteroids. Up to 10,000 bacteroids are densely packed within one infected cell.

Bacteroids are generally rod-shaped. However, they may take on different shapes as determined by the plant host. Bradyrhizobial bacteroids in peanut nodules are spherical, whereas the same strain on cowpea forms rod-shaped bacteroids. Clover and pea bacteroids have pleomorphic or club shape, and they are very sensitive to osmotic stress. It is this type of bacteroid that has led to the erroneous generalization that bacteroids are terminal cell forms incapable of reproduction. On the contrary, bacteroids from many plants very efficiently form colonies on appropriate agar media.

In the nodules of the Phaseoleae, Fabaeae, and Trifolieae, not all of the cells in the infected region of the maturing nodule are filled with bacteria. The others, the uninfected cells, differentiate to carry out steps in the nitrogen assimilation pathway that are downstream of the initial steps carried out within the infected cells. The bacteria-filled cells assume a distinctly cooperative metabolism and chemical environment that allows nitrogen fixation in the bacteria, as well as assimilation of the fixed nitrogen transported from the bacteria on the plant side. This physiology is outlined in the section titled 'Physiology of rhizobial symbiotic nitrogen fixation' below.

Integration and Regulation of Nodule Development

Rhizobial mutants defective in infection have revealed that nodule differentiation depends on infection. The degree to which this is true varies from one host to another. Some hosts (e.g., pea) form almost no nodule tissue unless infection is sustained beyond the root hair. Others (e.g., alfalfa or bean) can undergo organogenesis in response to noninfective rhizobial mutants, but exhibit anatomy and cytological differentiation that are quite distinct or incomplete compared to normal nodule development. Researchers working with some of these plants (e.g., bean and *Lotus* spp.) refer to the resulting structures as pseudonodules to emphasize the underdevelopment and deviation from normal development. Although pseudonodules result from infections on bean that do not progress into cell layers below the root hair, almost normal anatomy results if infection stops only a few cell layers further, well short of the stage at which bacteria are released from infection threads.

Nodule development is controlled by the plant according to at least two factors. One factor is whether the legume senses nitrogen limitation. Both development of nodules and feeding of the rhizobia to allow nitrogen fixation are energy-intensive processes. Perhaps because of the energy cost, the plant does not enter into symbiosis if soil has an excess of fixed nitrogen. Plants also repress nodule formation on some root sites according to whether other nodules are already forming nearby on the root. Nodule development generally initiates only in immature portions of the root where root hairs are just emerging. Nodules developing in older portions of the root will suppress nodule formation in younger portions. This is sometimes called autoregulation of nodule development. Autoregulation leads to optimal spacing of nodules that prevents wasteful unchecked nodule formation, but at a certain distance allows further nodulation as the plant grows and its need for nitrogen increases.

Deviations From the Foregoing Model

Infection Not in Root Hairs; Crack Entry

Some legumes do not have root hairs but still nodulate. Even those that do form root hairs may not have infection via root hairs. One alternate mechanism is that rhizobia enter at cracks in the root epidermis at the base of lateral root emergence. This process is sometimes referred to as crack entry. On certain legumes, the bacteria enter at other types of wounds, cracks, or, on some plants, by penetration between the cells of initially intact epidermal surfaces. *Azorhizobium caulinodans* ORS5721 is a microsymbiont of the water tolerant tropical legume *Sesbania rostrata* which forms N_2 fixing nodules on the roots and stems of the host legume via crack entry. These root nodules are formed at the curled root hair under well-aerated conditions whereas they occur at the base of lateral roots under hydroponic conditions. During crack entry, bacteria proliferate either in the epidermal fissures at the lateral root base or at the adventitious root primordia on the stems. Cortical infection pockets are formed by Nod factor-dependent local cell death induction and subsequent colonization of bacteria. From the infection pockets, infection threads guide bacteria towards the cells in nodule primordia for symbiotic uptake.

No Symbiosomes; Fixation Threads

The formation of symbiosomes represents a key step in the evolution of legume nodule symbiosis, as symbiosomes facilitate metabolite exchange between the two symbionts. Symbiosome formation does not occur in nodules formed on legume species that form a primitive symbiosis (e.g., *Andira* spp., many species belonging to the *Fabaceae* subfamily *Caesalpinioideae*) and *Parasponia* spp. (the only nonlegume species that can establish a symbiosis with rhizobia). *Rhizobium* bacteria in these species are not released into the nodule host cells but remain in infection threads, called fixation threads, which are enclosed by a cell-wall-like structure. Rhizobia fix atmospheric nitrogen within these fixation threads. As nodules mature, the infection threads enlarge greatly within plant cells inside the nodule cortex, allowing bacterial proliferation inside this engorged thread. In this state, nitrogen fixation

occurs within the bacteria, and the fixed nitrogen presumably is transferred into the surrounding cytoplasm. Such structures are known as fixation threads.

Infections Between Cell Walls, Not as Threads That Penetrate Plant Cells

In some legumes, infection threads that travel through plant cells are not observed. Instead, the infection is channeled between plant cells until the point at which bacteria enter cells in large numbers within either symbiosomes or fixation threads. Some crack-entry infections are of this type; but, on some plants, infections may start between cells and later develop true infection threads. In perhaps 25% of all nodulating legumes, infections are not observed in root hairs, and true infection threads do not develop.

All Plant Cells in the Central Infected Zone Fill With Bacteroids

In the paradigm above, it is considered very important for nitrogen assimilation by the plant that development give rise to specialized uninfected cells in the central, nitrogen-fixing zone of the nodule. Such cells are thought to channel the nitrogen-containing carbon compounds to the vasculature so that the nitrogen can be transported to the shoot. In plants that use ureide compounds for this purpose (soybeans, beans, and cowpea), the final steps of synthesizing the transport compounds occur in these specialized uninfected cells. However, this division of labor is not found uniformly in all legumes; there are tribes of legumes in which all the cells in the central nitrogen-fixing zone are infected.

Nod Factor Not Needed

Existence of alternative Nod factor (NF)-independent symbiosis between legumes and rhizobia was first recognized in two *Aeschynomene* species (*A. indica* and *A. evenia*), a genus in the Papilionoideae nodulated by photosynthetic bradyrhizobia (BTai1 and ORS278) deficient in the canonical *nodABC* genes. Another Bradyrhizobial strain that nodulates these two species does have nod genes. However, mutation of its nod genes does not prevent nodulation of these plants, whereas nod mutations do prevent its nodulation of certain other species of *Aeschynomene*. These latter species cannot be nodulated by strains BTai1 and ORS278. It is very interesting that these strains lack identifiable nod genes, but thus far the lack of this requirement in these particular symbioses cannot be correlated with any marked difference in the nodulation process. *Aeschynomene* species support infection by crack entry, without true infection threads, but rhizobial nod mutants on other hosts with these characteristics have failed to nodulate. The fact that Nod factors are not involved in the *Aeschynomene-Bradyrhizobium* spp. interaction suggests existence of alternative molecular dialogues in the legume family. Recent research indicated that CCaMK (Ca^{2+} /Calmodulin-Dependent Kinase), SYMRK (*Symbiosis Receptor Kinase*) and HK1 (Histidine Kinase 1) are obligatory for efficient nodulation in *Aeschynomene evenia*. CCaMK and SYMRK are recruited in Nod factor-independent symbiosis and hence conserved in all vascular plant endosymbioses described so far.

Stem Nodules

Certain water-tolerant legumes such as *Aeschynomene* and *Sesbania* (Fig. 2) form nodules on stems and on roots. The processes of nodule formation on the stems in these two plants exhibit many differences, but in both cases infections start where adventitious roots emerge from the stem, in a variation of the theme of crack entry. The two exceptional *Aeschynomene* species (*A. indica* and *A. evenia*) do not require *nod* genes of the rhizobia for either stem or root nodulation. However, *Sesbania rostrata* does not nodulate on stems or roots if its rhizobial partner lacks *nod* genes. Interestingly, under some conditions on this latter plant, root nodules also start by infections in curled root hairs. The same bacterium (*Azorhizobium caulinodans*) is accepted by the plant under all these variants of nodulation, although a wide variety of other rhizobia may also nodulate the roots.

Parasponia

Nodulation of the nonlegume genus *Parasponia* by rhizobia has many of the above 'deviant' properties. The rhizobia enters between epidermal cells and, as the bacteria penetrate deeper, true infection threads may form. Nitrogen fixation occurs in fixation threads. One additional property distinguishes *Parasponia* nodules from all known legume nodules. In the mature nodule, the infected cells, those that harbor the large fixation threads, are in the periphery (the nodule cortex) and vasculature develops in the center as it does in roots. This is the reverse of one property that appears to be true of all legume nodules: the infected nitrogen-fixing cells are central, with the vasculature being peripheral. In this respect, *Parasponia* nodule development is like that of the nodules of hosts of the actinorhizal bacterial genus *Frankia*. The presence of nod genes has been confirmed in rhizobia that infect *Parasponia* in all cases examined for this property. When the *nod* genes of one of these strains were mutated, it could not nodulate *Parasponia* or its legume hosts siratro and cowpea.

In all of these cases, it is the plant that determines these differences in nodule development; the differences assort with membership in different legume taxonomic groups. In contrast, a given rhizobial strain (usually a *Bradyrhizobium* strain) can nodulate and fix nitrogen on plants showing different modes of nodule development and infection, for example, crack-entry on

peanut and root hair infection on cowpea. Whether the set of bacterial genes and components required is any different on these different hosts is for the most part undetermined.

Although the issues of infection threads and fixation threads have been addressed in recent sampling of the Caesalpinioideae, the issues of root hair infection and the requirement for Nod factor have hardly been addressed at all. It is important to do so, to assess whether or not the evolution of Nod factor was central to the early evolution of the symbiosis. Many of the variations in nodule development appear to be exclusively controlled by the plant, but Nod factor obviously required evolution involving the bacteria. Similarly, it would be revealing to investigate the requirements for bacterial polysaccharides (see 'Rhizobial genes and components required in symbiosis' and 'Other properties of the rhizobia') in the symbioses of the Caesalpinioideae. In general, the theory of nodule development would benefit from investigating mutants of the rhizobia that form symbioses with properties that deviate from those of the paradigm described above.

Physiology of Rhizobial Symbiotic Nitrogen Fixation

Nitrogen fixation in legume nodules occurs within the bacteria inside specialized plant cells in the central region of mature nodules. Where they are carrying out nitrogen fixation, rhizobia are known as bacteroids, a term that has already been introduced in connection with nodule development. Functioning bacteroids must have the enzyme machinery for carrying out nitrogen fixation, encoded by *nif* genes, and the specialized catabolic and respiratory components that supply energy and electrons for the nitrogen fixation reaction, encoded by *fix* genes. In addition, they must have a compatible cell surface and transport systems for the exchange of metabolites that characterize the symbiosis. Once again, it should be emphasized that what is known is mainly from studies of the important agricultural legumes in the Papilionoideae.

The enzyme dinitrogenase catalyzes the ultimate reaction of nitrogen fixation:

The electrons are delivered at high energy potential to dinitrogenase from internal reductants by a second enzyme known as dinitrogenase reductase in a reaction that requires the hydrolysis of two ATP to two ADP and two phosphates for each electron transferred. Dinitrogenase and dinitrogenase reductase traditionally are considered as a complex known as nitrogenase. Although other nitrogenases called alternative nitrogenases exist in nature, to the extent surveyed, all nitrogen fixation in rhizobia is by the classical, and most widespread, dinitrogenase containing molybdenum. The immediate source of electrons for this reaction in at least some rhizobia appears to be a ferredoxin. Although the exact connection of this ferredoxin to the rest of bacteroid metabolism is still not clear, electrons for nitrogen fixation are provided by oxidation of dicarboxylates from the plant, and the energy (ATP) is generated by aerobic respiration (Fig. 5).

Oxygen Concentration, Microaerobic Metabolism, and Bacteroid Regulation

As nodule organogenesis and infection reach the mature stage at which nitrogen fixation begins, a marked gradient in oxygen concentration is generated across the nodule. In the central region where nitrogen fixation occurs, the infected cells' free oxygen concentration is 5–30 n mol l⁻¹, whereas a typical saturating aerobic concentration is 250 μmol l⁻¹. One factor that causes this extreme decrease in oxygen is the high population of rhizobia in the central zone of the nodule. Rhizobia are obligate respirers and use oxygen in preference to other terminal electron acceptors. Another factor appears to be the creation of oxygen diffusion barriers as the nodule differentiates, documented to exist particularly in the determinate nodules of the Phaseoleae. The anatomy responsible for attenuating oxygen diffusion appears to be an intercellular layer in the apoplastic spaces in the periphery of the nodule cortex. Importantly, this layer appears to be subject to regulation that somehow changes the underlying physical attributes according to physiological cues. A third important factor is leghemoglobin, an oxygen-binding plant protein present in high concentrations in the infected cells of the central nodule zone. Up to 30% of the soluble plant protein of a nodule is leghemoglobin, which is responsible for the characteristic red color of active nodules. As an oxygen-binding protein, it buffers the free oxygen to a low concentration consistent with its dissociation constant. At the same time, like myoglobin in animal muscle cells, leghemoglobin facilitates oxygen diffusion at a high rate within the complete consumption of this oxygen by rhizobial respiration prevents poisoning of nitrogenase, both enzymes of which are irreversibly inhibited by oxygen.

Because the concentration of free oxygen in the bacteroid environment is low, aerobic respiration by bacteroids requires a cytochrome oxidase with very high affinity for oxygen, the *cbb3* enzyme that is found in many Proteobacteria. It is encoded by genes named *fixNOPQ* in rhizobia. Another essential component in this symbiotic microaerobic respiratory chain is cytochrome *bc1*, whereas cytochrome *bc1* is not required by rhizobia for aerobic growth *ex planta* in media and conditions commonly used.

The low oxygen concentration provides the cue for regulation of *fix* and *nif* genes in the nodule, mainly through its effects on activity and synthesis of central regulatory proteins such as NifA, FixLJ, and others. Indeed, unlike for bacteria that fix nitrogen nonsymbiotically, nitrogen status within bacteroids appears to be largely irrelevant in regulating symbiotic nitrogen fixation. The logic of symbiotic regulation is developmental. Nitrogenase and other enzyme systems for bacteroid metabolism are induced when

Fig. 5 Coordination of plant and bacteroid metabolism. The leftmost third of this diagram depicts carbon metabolism. Sucrose in the infected plant cell is catabolized to malate, which enters the bacteroid via the Dct transport system and is oxidized by the Krebs cycle and ancillary reactions to yield CO₂ and 'electrons' (e⁻), mainly in the form of NADH. The middle third of the diagram depicts nitrogen fixation and assimilation. In some manner the electrons from catabolism reduce ferredoxins that in turn donate the electrons to nitrogenase for the reduction of N₂ to NH₃. Most of the fixed nitrogen may be excreted from the bacteroid as ammonium (NH₄⁺), but some may be incorporated into organic compounds diverted from the Krebs cycle to form amino acids that are transported to the plant cytosol (question marks in the diagram). The plant assimilates the nitrogen into nitrogen-rich carbon molecules such as asparagine and ureides (allantoin and allantoic acid) for transport in the xylem to the shoot. ATP for nitrogen fixation is generated by microaerobic respiration (rightmost third of the diagram). It is presumed that electrons enter the electron transport chain mainly as NADH from the Krebs cycle that reduces ubiquinone, whose reduction of oxygen is mediated by the bc₁ and cbb₃ respiratory complexes. Leghemoglobin (Lgb) in the plant cytosol maintains low free oxygen concentrations but mediates high oxygen flux to the bacteroids, where the high affinity of the cbb₃ oxidase pulls oxygen flux toward the bacteroid membrane. The electrochemical gradient of protons (ΔμH⁺) generated by the electron transport chain drives ATP synthesis via the bacteroid ATP synthase (Atp). © 2008 Dale Noel. Published by Elsevier Inc. All rights reserved.

development and infection have provided the optimum environment and plant components for nitrogen fixation by the bacteria and assimilation by the plant. Oxygen concentration is a simple cue for signaling that the proper stage has been achieved.

Regulation by low oxygen implies that these bacteroid metabolic pathways actually might not be unique to bacteroids, and that they can be induced *ex planta* under low oxygen. In general, this is indeed the case. Because the degree of induction of a particular *nif* or *fix* gene cluster often is much higher in the nodule than under microaerobic conditions *ex planta*, it is possible that additional factors are at play in the nodule.

Bacteroid Carbon Metabolism, Host Contributions, and Nitrogen Assimilation

The plant supplies the bacteroids with carbon compounds, whose oxidation in the bacteria releases electrons for the reduction of nitrogen and makes possible the microaerobic respiration that generates ATP needed to drive nitrogen fixation. In as much as rhizobia generally can use glucose as carbon source, it might be supposed that the sucrose provided to roots from shoot photosynthesis would be simply broken down to glucose for the bacteroids. Such is not the case, however. Instead, glucose and fructose in the nodules are catabolized to phosphoenolpyruvate and then carboxylated to form dicarboxylic acids. Bacteroid proliferation and nitrogen fixation are highly dependent on the ability of bacteroids to utilize dicarboxylic acids of the Krebs cycle (malate and succinate). This was suspected first based on physiological studies that tested the availability of different compounds to the bacteroids and their ability to utilize these and other potential carbon sources. Confirmation came with the isolation of rhizobial mutants defective in transport of dicarboxylates (Dct mutants). Such mutants typically fail in nodule development at the point of bacterial release from infection threads; as a consequence, the central zone of the nodule where nitrogen fixation should occur is very sparsely infected by such mutants.

Another carbon compound that is relatively abundant inside legume nodules is inositol. However, rhizobial mutants unable to utilize inositol do not show the severe defects of Dct mutants. Another property of bacteroids, nonessential for nitrogen fixation but perhaps evolutionarily important, is the tendency to store excess carbon as polyhydroxybutyrate or glycogen or both. Production of

these storage compounds begins in the infection thread and may provide ready fuel for the energy-demanding period of rapid bacteroid proliferation.

Nitrogenase activity produces ammonium. It is generally accepted that a significant portion of the ammonium is transported directly out of the bacteroid. However, there are many indirect indications that some portion of the fixed nitrogen first is incorporated into a carbon compound within the bacteroid and transported as an amino acid into the plant cytoplasm (Fig. 5). In the mature nodule, the bacteroids are not growing or reproducing. Hence they have little need for fixed nitrogen. Therefore, whether transported as ammonium or as amino acid, almost all of the nitrogen fixed by the bacteroids is ultimately assimilated by the plant to provide for the biosynthesis of nitrogen compounds needed during plant growth. This assimilation results in glutamine as an early product within the plant cells harboring bacteroids (Fig. 5). Generally, the nitrogen is passed from glutamine to other metabolites, resulting in a few abundant N-rich compounds, such as asparagine and ureides, for transport of the nitrogen via the xylem.

Just as the plant controls whether nodules will form, it also can inhibit nitrogen fixation by the bacteroids in response to sudden influxes of fixed nitrogen (e.g., nitrate) in the root environment. It appears that the underlying mechanism starves the bacteria of carbon or oxygen or both. This inhibition is reversible. For at least a week the inhibited nodules and their bacteroids retain full capacity such that, once the exogenous fixed nitrogen is used up or removed, nitrogen fixation activity is rapidly restored to levels observed before inhibition.

Rhizobial Genes and Components Required in Symbiosis

Nodulation

Aside from recently discovered exceptions mentioned earlier, the capability to incite nodules on host legumes has been shown to depend on rhizobial Nod factors (Fig. 3), whose key role in triggering nodule development have been delineated already. The production of these glycolipids (lipooligosaccharides) is specified by rhizobial *nod*, *nol*, and *noe* genes (collectively referred to as nod genes). Genes *nodA*, *nodB*, and *nodC* specify the Nod factor basic structure – the N-acetylglucosamine oligomer (*nodC*) and the fatty acyl adduct (*nodA* and *nodB*) (Fig. 3). *nodJ* genes are generally found in nod clusters as well; they are presumed to effect transport of the Nod factors out of the rhizobial cell.

Other nod genes provide strain-dependent features to Nod-factor structure (Fig. 3) that are presumed to contribute to host specificity of nodulation, efficiency of eliciting nodule initiation, and perhaps refinement of multiple roles of the Nod factor in promoting nodule development. For instance, different alleles of the *nodE* gene specify different unsaturated fatty acids attached as the lipid on the Nod factor. The *nodH* gene of *S. meliloti* specifies a sulfation of the Nod factor that is required for nodulation of *Medicago* species (including alfalfa). Mutation of the *nodL* gene of *R. leguminosarum* bv. *viciae* strains strongly decreases its nodulation of some of its normal hosts but has little effect on others.

Summed over all rhizobial strains, the number of genes associated with *nod* genes and shown (or suggested) to play an accessory role in nodulation is impressive, having run the entire alphabet on *nod*, *nol*, and almost on *noe*. As many as half of these genes may not affect Nod factor structure, but instead affect nodulation in other ways. The best characterized is *nodO*, which encodes a protein postulated to form cation-selective pores in the plant plasma membrane and thereby complement the plant response to Nod factors. It is dispensable for nodulation by wild-type *R. leguminosarum* bv. *viciae* in the laboratory, but is essential in strains that are mutated in *nodE*.

Transcription of the common and accessory *nod* genes is controlled by *nodD* genes. NodD proteins bind to nucleotide sequences called 'Nod boxes' upstream of the transcription start site of the various nod operons. In the presence of the flavonoids of the rhizobial host, NodD activates transcription. Certain other exuded plant compounds, aside from flavonoids, also have been shown to trigger nod induction.

The *nod* genes help to explain the host range of a rhizobial strain. The first factor is the combination of the rhizobial *nodD* and plant flavonoids; generally, they must be compatible to induce the other nod genes. The second factor is the Nod factor structure. A given plant generally responds only to a certain spectrum of structures. For example, modifications of Nod factor by previously mentioned genes *nodE*, *nodH*, and *nodL* can have important effects on the way in which legumes are nodulated by a given strain. In a given strain a mixture of Nod-factor structures is generally observed. This mixture can be relatively simple (e.g., in *S. meliloti*) or extremely complex (e.g., in *Sinorhizobium* spp. NGR234, whose plethora of Nod factors contributes to its broad host range). Interestingly, it is often found that the best known host of a strain does not require what appears to be a distinctive modification.

Even though Nod factor is essential for nodule formation on almost all legumes studied, it is important to realize that additional factors can be required to elicit observable nodule tissue. For instance, pea roots form hardly any nodule tissue if an *R. leguminosarum* strain is incapable of exopolysaccharide production. Soybean's response to a *Bradyrhizobium japonicum* mutant lacking lipopolysaccharide (LPS) O-antigen is similarly restricted. In this respect, polysaccharides and perhaps other molecules besides the Nod factor are crucial in determining the host range.

Homologous *nod* genes are found in the rhizobia of all known taxa, including those in the beta Proteobacteria. According to phylogeny based on rRNA sequences, the two strains without nod genes are located deeply within an outlying branch of the Bradyrhizobia. Whether or not nod was central to the earliest legume nodulation in evolution, it is obviously a hugely successful invention as deduced from its near ubiquity among studied rhizobia. Yet it seems to be confined to rhizobia (i.e., to legume nodulation). The presumptive coevolution of Nod factors, plant receptors, and downstream plant responses are subjects currently

Table 2 Nod genes and their predicted function

<i>Genes</i>	<i>Predicted functions</i>
<i>nodA</i>	Acyltransferase, nodulation protein
<i>nodB</i>	Nodulation chitooligosaccharide deacetylase
<i>nodC</i>	N-acetylglucosaminyltransferase
<i>nodD</i>	Transcriptional regulator, nodulation protein
<i>nodE</i>	Nodulation beta keto acyl ACP synthase
<i>nodF</i>	Nodulation acyl carrier protein
<i>nodG</i>	Nodulation protein, 3-ketoacyl-(acyl carrier protein) reductase
<i>nodH</i>	Sulfotransferase
<i>nodI</i>	Nodulation ATP binding protein
<i>nodJ</i>	Membrane transport nodulation protein
<i>nodL</i>	Putative nodulation protein
<i>nodM</i>	Glutamine-fructose-6 phosphate transaminase nodulation protein
<i>nodO</i>	Calcium ion binding nodulation protein
<i>nodP</i>	Nodulation protein, sulfate adenylate transferase, subunit 2
<i>nodQ</i>	Nodulation protein, sulfate adenylate transferase, subunit 1
<i>nodS</i>	Methyltransferase involved in Nod factor biosynthesis, nodulation protein
<i>nodT</i>	Putative exported nodulation protein
<i>nodX</i>	Putative nodulation protein, probable sugar acetylase
<i>nodZ</i>	Nodulation protein, fucosyltransferase
<i>nodK</i>	GDP-L- Fucose synthetase
<i>nodL</i>	Acetyltransferase
<i>nodO</i>	Nodulation protein
<i>nodR</i>	Transcriptional regulator
<i>nodT</i>	Nodulation protein
<i>nodU</i>	Nodulation protein
<i>nodV</i>	Nodulation protein
<i>nodW</i>	Nodulation protein
<i>nodX</i>	Nodulation protein
<i>noeA</i>	Host specific nodulation protein
<i>noeB</i>	Host specific nodulation protein
<i>noeC</i>	Nodulation protein
<i>noeK</i>	Phosphomannomutase
<i>noeL</i>	GDP-D-Mannose dehydratase

becoming amenable to research and may have implications for engineering other plants to enter into this type of symbiosis. Genes involved in the nodulation process with their predicted functions are enlisted in [Table 2](#).

Infection

Infection of course requires growing rhizobia capable of reproduction. Any mutation that prevents growth in the rhizosphere or infection thread will arrest infection. Bacterial auxotrophs may have problems on some symbiotic combinations but not on others. Presumably, this relates to whether the nutrients are available in sufficient quantities to the bacterium in the environment of the infection. It also may depend on the particular transport systems available and the pathways for scavenging biosynthetic end products, intermediates, and derivative compounds. On almost all hosts, rhizobial purine auxotrophs fail early in infection. Whether this arises from a special role for the purine biosynthesis pathway in symbiosis has not been established.

In most symbioses that have been studied, a bacterial-surface polysaccharide, often more than one type, is required for successful completion of the infection process. Examples include LPS O-antigens, cyclic glucans, acidic exopolysaccharides (EPS), and 'K-type' capsular polysaccharides. None of these is individually required at any particular stage in all symbioses.

Over the years of studying the agricultural legumes, a generalization has emerged regarding whether EPS is required in symbiosis. The Phaseoleae do not seem to require them, whereas infection of the Trifolieae and Fabae generally are very limited unless the bacterium is capable of producing its major acidic EPS. The structural basis for this requirement is best understood for the *S. meliloti*-alfalfa symbiosis. The main EPS of *S. meliloti* is known as succinoglycan, the bulk of which is produced by the bacterium *ex planta* as long polymers of a repeat unit composed of eight sugars modified on some residues by acetyl, pyruvyl, and succinyl groups. However, in symbiosis, the active form is believed to be the succinylated oligomers (monomers, dimers, and trimers) of the octasaccharide repeat unit. Perhaps it acts as a diffusible signal compound but its exact role is unknown. One clue might be that high production of either a different EPS (galactoglycan) or a K-type capsular polysaccharide can substitute for succinoglycan on some

hosts of *S. meliloti*. Many investigators speculate that EPS and other polysaccharides somehow suppress host-defense responses that otherwise would arrest rhizobial infection.

On legumes in all of these tribes, *Rhizobium* and *Bradyrhizobium* symbionts are required to produce LPS O-antigen. On hosts in the Trifolieae and Fabeae, this requirement occurs late in the infection process, whereas on the Phaseoleae the requirement comes about very early. O-antigen-containing LPS from *A. caulinodans* is proposed to act as a diffusible signal in nodule development on *Sesbania*. In several of the symbioses, the LPS has been shown to undergo changes during the interaction with the plant. In some cases, the same plant compounds that trigger nod induction also trigger changes in LPS. *Sinorhizobium fredii* strains may undergo the greatest change. Strain NGR234 produces an entirely new O-antigen in response to a nod inducer. As proposed for EPS, LPS O-antigens possibly suppress host defenses. The phenotypes of deficient mutants suggest that they also may serve as ligands for plant receptors in sustaining infection and/or for endocytotic release at the end of infection.

There has been limited study of the requirement for these polysaccharides on hosts highly diverged from the agricultural Papilionoideae legumes. Requirement of both LPS O-antigen and EPS in the infection of some legumes in the Mimosoideae have been inferred from singular mutants of certain rhizobial symbionts.

Nitrogen Fixation and Oxygen-Responsive Regulation

Rhizobial *nif* genes are those that are homologous to genes required for synthesis and function of nitrogenase in nonsymbiotic bacteria. For instance, *nifKD* genes encode the protein subunits of dinitrogenase, and *nifH* encodes the polypeptide of nitrogenase reductase. *nifBEN* genes specify the proteins needed to produce the iron-molybdenum cofactor of dinitrogenase. In addition, as in all Proteobacterial nitrogen-fixing bacteria, the regulatory gene *nifA* is invariably present.

fix genes are additional genes needed for symbiotic nitrogen fixation. For instance, the *cbb3* cytochrome oxidase that has high affinity for oxygen is encoded by genes *fixNOQP*. This operon is generally followed on the DNA by the *fixGHIS* operon, whose function has not been established in detail but is believed to be in the transport of copper and perhaps its insertion into the *cbb3* enzyme. Other *fix* genes generally present are *fixABCX*, whose function still has not been established. One or more of the regulatory genes *fixLJ* and *fixK* usually are present as well.

Although usually not termed *fix* genes, the *dct* genes fit the definition of *fix* genes noted above. They are needed for uptake of most of the carbon supplied by the plant, which is in the form of Krebs-cycle dicarboxylates, mainly succinate and malate (Fig. 5). All rhizobia in which they have been mutated become deficient in nitrogen fixation (as well as bacteroid proliferation). Also of utmost importance are the genes for the enzymes of the Krebs cycle and associated reactions needed to catabolize the carbon supplied by the plant. Interestingly, in certain rhizobia, some of the enzymes of the Krebs cycle can be eliminated by mutation without severely affecting nitrogen fixation. One explanation is that pathway shunts can bypass a given step(s). Even though the enzyme for this step is normally present and active, this metabolic plasticity compensates if the activity is lost. Such plasticity may have evolved to allow rapid adaptation to changing conditions of carbon and oxygen supply. Another explanation is that not all steps in the Krebs cycle are needed if ammonium is incorporated into one of the metabolites and then exported into the plant cytoplasm (Fig. 5).

It has been stated already that symbiotic nitrogen fixation is regulated according to oxygen concentration. In all systems the NifA protein is a positive regulator that activates the transcription of other *nif* genes. In classical rhizobia this protein is inhibited directly by oxygen. Transcription of the *nifA* gene also is controlled according to oxygen concentration. In *Sinorhizobium*, this control is exerted via proteins FixL and FixJ. FixL is an oxygen sensor that under low oxygen activates FixJ, which is a transcriptional activator of *nifA* and certain other genes. In *Bradyrhizobium*, the corresponding control is via RegS and RegR, which respond to respiratory electron flow to activate transcription of *nifA*. In both *Bradyrhizobium* and *Sinorhizobium*, the other *fix* genes are controlled by FixK protein; transcription of *fixK* is controlled according to oxygen concentration, through regulation by FixL and FixJ (Table 3).

Rhizobial Genomes and Genetics

Genomes

The total nucleotide sequences of multiple rhizobial genomes have been determined till date along with their complete plasmid profile. The known whole genomes represent four genera of the 'classical' rhizobia: *Rhizobium* (*R. leguminosarum* 3841 and *R. etli* CFN42), *Sinorhizobium* (*S. meliloti* 1021), *Mesorhizobium* (*M. loti* MAFF303099), and *Bradyrhizobium* (*B. japonicum* 110 and the photosynthetic *Bradyrhizobial* strains BTAi1 and ORS278 mentioned earlier). All of these rhizobial strains have larger than average bacterial genomes, ranging from 6.5 to 9.1 Mb (1 Mb=106 nucleotides). Genome information of the members of four representative rhizobial genera are depicted in Table 4.

Plasmids

Plasmids are bacterial DNA molecules that are smaller than the chromosome(s). Generally, they are dispensable for bacterial growth at least under some conditions. Instead, they typically encode properties that allow growth or otherwise give the bacteria selective advantages under niche-specific conditions. In some rhizobia (e.g., *Rhizobium* and *Sinorhizobium* species) *nod*, *nif*, and *fix* genes are

Table 3 Nif and fix genes and their predicted functions

<i>Genes</i>	<i>Predicted function</i>
<i>nifA</i>	Nif- specific regulatory protein, transcriptional activator

found on a plasmid termed the symbiotic plasmid. This plasmid is distinct in each strain, having a different size and different additional genes that have no apparent role in symbiosis. These other genes generally outnumber the genes devoted to the symbiosis. In *Bradyrhizobium* and *Mesorhizobium* species, the *nod*, *nif*, and *fix* genes are found on the chromosome.

In some of the rhizobia, a significant portion of the genome is contained on plasmids. Plasmids larger than 1 Mb arbitrarily are termed megaplastids. *S. meliloti* has two of them, which account for almost half of its 6.7 Mb genome. Plasmid A is 1.35 Mb and plasmid B is 1.68 Mb. These plasmids are larger than the entire genomes of many obligately symbiotic bacteria and even some free-living bacteria. Plasmid A is the typical symbiotic plasmid with *nod*, *nif* and *fix* genes, whereas plasmid B has genes for exopolysaccharides required in the symbioses of this species.

In the two *Rhizobium* strains whose entire genomic nucleotide sequences have been determined, the plasmids are smaller, but there are more of them. Strain *R. leguminosarum* 3841 has 6 plasmids which account for about 40% of the 7.8 Mb genome. Strain *R. etli* CFN42 also has six plasmids that account for about one third of the 6.5 Mb total genome. In both of these strains, one of the plasmids is a typical symbiotic plasmid carrying the *nod*, *nif*, and *fix* genes, as well as genes not required in the symbiosis.

Duplicated Genes

The classical rhizobia have a high incidence of duplicated genes, genes that are not merely homologous, but sometimes have near identity of nucleotide sequence. This creates a problem in analyzing gene function by mutation. Often mutating a gene has no effect because there is an isofunctional duplicated gene (paralog) compensating for its loss. Potentially, a new function can evolve in one of the paralogs of each set of duplicated genes. Therefore, rhizobia appear to have a very rich potential for evolution of new functions. Whether they are atypical in this respect among bacteria is not clear, but they were among the first bacteria in which a high rate of duplications was recognized and studied in detail.

Mobile Genetic Elements

One explanation for the diversity of the rhizobia is that genes for symbiosis can be transferred from bacteria of one species to those of another species. Studies of genetic sequences strongly support this notion. Emerging examples are the rhizobia belonging to the beta Proteobacteria. Studies so far indicate that their *nod* and *fix* genes have been acquired more than once in evolution and from different sources within the rhizobia of the alpha Proteobacteria. Although sequence divergence indicates that these events happened long ago, studies among the rhizobia of the alpha Proteobacteria document that genetic transfers of clusters of symbiotic genes are occurring at readily detectable rates all the time in the soil. Most studies have documented transfers among strains in the same species, but transfers between genera have been reported as well. With the modern techniques of microbial ecology, it is possible to detect and isolate 'nonsymbiotic' rhizobia, rhizobia whose genomes belong to a particular rhizobial species, but lack *nod*, *nif* and *fix* genes. Moreover, it has been possible to demonstrate that within a given period of time, such strains introduced into the soil had picked up symbiotic gene clusters from rhizobia that were indigenous or also introduced into the soil at the same or different times. Such transfers have been demonstrated in the laboratory as well.

In retrospect, these observations are not at all surprising. Rhizobia harbor types of mobile genetic elements that are known to foster such transfers in other bacteria, and, indeed, they provide some of the best case studies for such genetic mobility in nature. Although the emphasis in rhizobia is almost always on symbiotic properties, such exchanges between rhizobia and other bacteria are not limited to symbiotic gene clusters. It is very common for bacteria to acquire in this way genes that allow growth in special niches that are not always encountered by the species. The spread of pathogenesis, antibiotic resistance, and utilization of aromatic carbon compounds are notable examples found in other bacteria. The common transfer agents and mechanisms include conjugative plasmids, conjugative symbiosis islands, specialized transduction of genes on proviruses, and insertion elements that border genetic islands and translocate them to new DNA. Studies of the rhizobia have demonstrated at least three of these mechanisms: mobilization via plasmids, symbiosis islands, and translocations mediated by insertion elements. In the genera containing symbiotic gene clusters on plasmids (e.g., *Rhizobium*, *Ensifer* (*Sinorhizobium*)), plasmid-mediated conjugation appears to be a main mechanism of the spread of symbiotic determinants and changes in host specificity. Even when the symbiotic plasmid is not a conjugative plasmid, it is mobilized by another indigenous plasmid that is conjugative. Examples include the changes in biovars among *R. leguminosarum* mentioned in the section titled 'Rhizobial host ranges'. In *Bradyrhizobium* and *Mesorhizobium*, symbiotic genes are instead found on the chromosome in genetic clusters known as symbiotic islands. They can be recognized in *Bradyrhizobium* strains but in most cases the conjugative transfer elements that moved them into the strains have become inactive during evolution. However, in *Mesorhizobium loti* the transfer functions are still active. This species has been a model for demonstrating the transfer of symbiotic islands in both the field and the lab.

Genetic Analysis of Rhizobia

Rhizobia have many natural agents for achieving genetic change. They have the conjugative elements noted above, and, like other forms of life, rhizobia are afflicted by viruses and insertion elements. These agents have been very important in shaping the genomes of present-day strains, but, except for a few viruses, they have not been exploited as tools for genetic analysis. Instead most such tools

were developed for use in other Proteobacteria and then adapted for use in rhizobia. One example has been the extremely useful transposon Tn5, which is the workhorse mutagen for obtaining null mutations in the initial study of a particular rhizobial property. In rhizobia, Tn5 inserts itself in a relatively random manner at sites throughout the genome, generally at only one location per mutant strain. The resulting insertions are very stable (rarely revert), and, very importantly, Tn5 and its man-made derivatives carry various antibiotic-resistance genes that tag genes for selecting a mutation with no other selectable phenotype in matings and cloning. Broad- and narrow-host conjugative plasmids isolated from other bacteria also have been key genetic tools. They work as vectors to shuttle DNA between *Escherichia coli* (or sometimes other bacteria) and rhizobia. The narrow-host plasmids can be transferred to rhizobia, but do not replicate in them. They serve to introduce transposons or to force molecular recombination between transferred rhizobial DNA and resident DNA in the recipient rhizobial genome. This has allowed replacement of resident wild-type DNA with mutant alleles constructed in vitro. The broad-host plasmids do replicate in rhizobia and allow multiple copies of introduced DNA to be maintained in the recipient rhizobia for testing genetic complementation. Such plasmids can be used to transfer DNA between rhizobia as well. In studies of some rhizobia, notably *S. meliloti* and *R. leguminosarum*, generalized transducing phage (viruses) have been developed for this same purpose.

Other Properties of the Rhizobia

Common Traits

Generalizations about rhizobia can be made, with the caveat that there will be exceptions among a group this diverse. All characterized rhizobia are Gram-negative rods that are catalase- and 'oxidase'-positive. They have flagellar motility and exhibit chemotaxis. All of the classical rhizobia can carry out hexose catabolism by the Entner-Duodoroff pathway. Gluconeogenesis, pentose phosphate and glyoxylate pathway do exists while Embden Meyerhof Parnas pathway seems to be virtually absent with *Bradyrhizobium japonicum* being an exception. In keeping with the catabolism needed in symbiosis, all have complete Krebs cycles and associated anaplerotic reactions so that organic acids can be used for growth.

Considered obligate respirers, all can use oxygen, and most also use at least nitrate as the terminal electron acceptor. Rhizobia grow well microaerobically. A key enzyme for this growth, the *cbb3* cytochrome oxidase, is an example of a function encoded by *fix* genes important in symbiosis but also induced under microaerobic conditions that rhizobia may encounter in the soil (and fresh water environments) in the absence of the plant. The *cbb3* oxidase is widely distributed among related Proteobacteria that are not known to form symbioses with eukaryotes, for instance, the purple phototrophs.

A point to be emphasized is that rhizobial populations persist indefinitely in the soil as part of the overall bacterial population, and they do so regardless of the presence of the host plant. Therefore, they have capabilities that allow growth in this environment. Like 'pseudomonad' soil bacteria, individual rhizobial strains that have been studied in the laboratory are extremely versatile heterotrophs, able to use a plethora of carbon sources, including sugars, organic acids, amino acids, and phenolics. Total genomic nucleotide sequences bear this out. The genomes are consistently large relative to the average bacterium and have a wealth of annotated genes devoted to diverse catabolic pathways and transmembrane transport systems. They utilize diverse nitrogen sources as well, including molecular nitrogen (mainly in symbiosis), ammonia, nitrate, nitrite, and amino acids. Aside from versatile heterotrophy, they all seem proficient at biosynthesis of amino acids, nucleotides, and other small molecules needed for growth. Certain vitamins, in contrast, greatly stimulate rhizobial growth. Hence, they can be grown in the laboratory on a wide variety of simple defined minimal media with one carbon source, a nitrogen source, salts, and certain vitamins. They also do well on defined and undefined rich media. How well they do depends on the genus and the composition of the particular medium. In general, the classical rhizobia require a relatively high calcium concentration for growth.

Rhizobia are commonly obtained as clonal isolates from nodules by requiring colony formation on agar containing yeast extract and mannitol. As a link to older literature that categorized rhizobia according to growth rate, the 'fast growers' on this medium include the classical genera *Rhizobium* and *Sinorhizobium*. *Bradyrhizobium* strains are 'slow growers,' and *Mesorhizobium* strains are said to exhibit intermediate growth rates. If there are legume symbionts that do not grow on yeast extract-mannitol medium, they would have been missed in most studies because of the presumption that legume isolates will grow on this medium.

Polysaccharides

Historically, there has been great interest in the surface polysaccharides produced by the rhizobia, because of the likelihood that interactions between these bacteria and legume cells, as well as other biological entities, involve molecules on the rhizobial surfaces. However, the full spectrum of polysaccharides produced by any rhizobial strain has never been identified completely. Genome annotations indicate a staggering number of gene clusters apparently devoted to polysaccharides. Long before their genetics were known, certain polysaccharides, including many EPSs that are important in symbiosis, were studied biochemically because they were the most abundant of a particular class of polysaccharides. In other cases, a polysaccharide was first studied as a result of mutations that caused a deficiency in symbiosis, which was traced to a deficiency in that polysaccharide. Genes for LPS O-antigens, cyclic glucans, and some capsular polysaccharides have been discovered in this way. The functions of these polysaccharides, aside from requirements in symbiosis, have, for the most part, undergone little scrutiny. Hypothetical roles include protection against desiccation, environmental toxins, and plant defenses. They may help evade viruses, but there are cases where viruses have evolved to use them as receptors for the first step in infection. Most divisive among the proposed EPS functions is its role as a signaling

molecule triggering plant developmental response and as a determinant of host specificity. There is a strong proposition that production of a variety of symbiotically active polysaccharides permits rhizobial strains to adapt to changing environmental conditions as well as to interact efficiently with legumes.

Rhizobia, particularly in the genus *Rhizobium*, produce impressive amounts of exopolysaccharide on carbon-rich media such as yeast-mannitol. Within a few days after appearing on inverted agar plates containing this medium, colonies will drip copious slime onto the Petri dish cover even if stored at 4°C. Outside the symbiosis, EPSs are regulated according to exogenous carbon/nitrogen ratios; that is, excess carbon leads to high EPS production. Much of the total production occurs after the net growth of a culture or colony has ceased. The structures of several rhizobial EPSs have been determined. Each genus makes a structurally distinct major EPS, whereas within a genus, the most abundant EPS in all species may be very similar. Most common rhizobial EPS is succinoglycan (EPS I) produced by several *S. meliloti* strains composed of octasaccharide repeating units containing one galactose and seven glucose residues (in molar ratio 1:7). These are joined by β -1,3, β -1,4 and β -1,6 glycosidic linkages. Single repeating unit is adorned by acetyl, pyruvyl and succinyl groups. *S. meliloti* has the ability to produce another distinctive exopolysaccharide termed galactoglucan or EPS II. EPS II is synthesized only under phosphate starvation or when mutation in one of the regulatory genes, either *mucR* or *expR* occurs. It differs significantly in structure from EPS I as it is a polymer of disaccharide repeating unit composed of an acetylated glucose and one pyruvylated galactose coupled by α -1,3 and β -1,3 glycosidic bonds. EPS I and EPS II produced by the wild-type *S. meliloti* strain 1021 are symbiotically active exopolysaccharides. *Rhizobium leguminosarum* strains, have the same octasaccharide conserved repeating unit of EPS, composed of glucose, glucuronic acid and galactose (in the molar ratio of 5:2:1) even though they included into different biovars (i.e., *trifolii* and *viciae*) and nodulate different plant hosts. Nevertheless, certain strains of *R. leguminosarum* secrete EPS, the repeating unit of which differs in sugar content and the length of the side chain. In *R. trifolii* 4S, the EPS subunit with seven sugars lacking terminal galactose from the side chain has been described while in *Rhizobium leguminosarum* bv. *viciae* 248 the repeating unit with additional glucuronic acid in the side chain has been reported. Nevertheless, all the EPSs mentioned above are similar by means of possessing identical backbones and the same β -1,6 linked glucosyl residue starting the side chain. The pattern of non-sugar decoration with acetyl, pyruvyl and hydroxybutanoyl residues was found to be different for several *R. leguminosarum* strains.

exo/exs or *pss* genes governing exopolysaccharides biosynthesis form large clusters located either on the chromosome or on megaplasmids. Such proteins are transferases which assembles EPS repeating units, synthesizes nucleotide sugar precursors and enzymes involved in adding non sugar moieties to EPS. in addition to polymerization and export of the growing EPS chain onto the cell surface. EPS biosynthesis represents a multi-step process which depends on activity of a protein complex localized both in the inner and outer membrane. Specific glycosyltransferases function in transferring precursors and nucleotide diphospho-sugars to growing polysaccharide chain attached to an acceptor. Undecaprenol diphosphate was identified as a sugar acceptor in the case of most heteropolysaccharides. The repeating unit is formed at the inner leaflet of the cytoplasmic membrane while the individual repeating units gets polymerized at the periplasmic face of the inner membrane after they have been flipped across the IM by flippase. Polymerization is thought to be coupled to export of the growing polymer to the cell surface and engages Wzy-like polymerase and Wzc-like inner membrane-periplasmic auxiliary protein (MPA) with an ABC module which controls chain length of the growing heteropolymer. Outer membrane auxiliary protein (OMA) facilitates the growing polysaccharide to reach the cell surface by forming a channel in the outer membrane, thereby completing the process of translocation. Effective EPS translocation is the result of physical association of the proteins localized in both membranes.

EPS synthesis and regulation of EPS I produced by *S. meliloti* has been studied in detail while data concerning synthesis of acidic exopolysaccharide in *R. leguminosarum* are more patchy. EPS biosynthesis in *Rhizobium* is a highly complex process regulated at both transcriptional and posttranslational levels and influenced by multiple environmental conditions. Extensive genetic studies have resulted in identification of several regulators like *exoR*, *exoS*, *mucR*, *expR*, *syrM* and *exoD* mapped on the chromosome and *exoX*, *exsB* and *expG* genes on the second megaplasmid, pSymB regulating EPS I and EPS II synthesis in *S. meliloti*.

Notable Traits Found in Some Rhizobia

In view of the phylogenetic diversity of these bacteria, it is not surprising that various rhizobial species have capabilities that appear to be uncharacteristic of the majority. For instance, *A. caulinodans* and *Burkholderia phymatum* can grow ex planta with N₂ fixation as the sole nitrogen source. Several other rhizobia have been shown to induce *nif* genes and even to produce functional nitrogenase, but indefinite growth dependent solely on nitrogen fixation has not been observed otherwise. The impact in nature of this nonsymbiotic nitrogen fixation is unclear, but is probably trivial compared with the fixation by these bacteria inside legume nodules.

Many rhizobia appear to harbor ribulose biphosphate carboxylase and perhaps other enzymes of the Calvin cycle. A few have been demonstrated to grow autotrophically, particularly with hydrogen as the lithotrophic energy source. As mentioned above, there are also certain Bradyrhizobia that appear to be capable of phototrophy. *Methylobacterium nodulans* is described to be the only rhizobial species capable of growth on certain one-carbon compounds including methanol, although it is not clear how many legume nodule isolates have been tested for this property.

S. meliloti survives remarkably well under very dry conditions, an exceptional property that is exploited in using it as a commercial inoculant of alfalfa. This property may be shared among other *Sinorhizobium* (*Ensifer*) species. The survival is not due

to spore formation. None of the rhizobia is known to form spores, and other classical rhizobia used in agriculture must be carefully maintained at certain moisture levels to assure sufficient viability at the time of inoculation of designated crops. The basis of this property in *S. meliloti* is under active investigation in parallel with long-term projects aimed at increasing the desiccation tolerance of other agronomically important rhizobia.

Rhizobia are not particularly acid tolerant. *S. meliloti* is among the most acid-sensitive, showing growth inhibition at pH values below 6. Among the most acid tolerant are *Rhizobium tropici* and some Bradyrhizobia, which survive at pH 4.5.

Succinate Mediated Catabolite Repression

Rhizobia may be free living and symbiotic rhizobia in nature with the capability to utilize variety of carbon compounds thereby raising the aspect of catabolite repression control. Preliminary studies on *R. meliloti* have showed that it can utilize wide range of sugars and TCA cycle intermediates and the presence of succinate can inhibit sugar uptake and metabolism by limiting α -glucosidase, β -glucosidase and β -galactosidase activity. Glucose catabolism enzymes in *Rhizobium sp.* and *Bradyrhizobium sp.* are inducible in nature with succinate repressing the glucose catabolic enzymes in a cAMP independent manner. *S. meliloti* 2011 does not show diauxie when grown on lactose plus other sugars like maltose, sucrose or glucose which was however apparent when cells were grown on succinate along with sugars like lactose, maltose and cellobiose. Addition of succinate to the culture growing in lactose, abruptly decreased β -galactosidase and β -glucosidase activities. Presence of succinate influence the levels of ED and EMP pathway enzymes in many rhizobia. Hence, it can be concluded that by repressing the uptake and utilization of other non-preferential carbon sources, dicarboxylates like succinate may influence multiple metabolic functions of *Rhizobium sp.* This repression has been termed as Succinate mediated catabolite repression (SMCR).

Plant Growth Promotion

Multiple reports have shown various direct and indirect mechanisms of plant growth promotion by rhizobia with the ability to fix N being the most exploited one. Efficiency of N fixed by legumes varies, depending on the host genotype, efficiency of rhizobia harboring the host and soil and climatic factors. Reported quantum of N fixation ranged from 126 to 319 kg N ha⁻¹ and 33–643 kg N ha⁻¹ in groundnut and soybean respectively with 77–92 kg N ha⁻¹ in pigeon pea, 25–100 kg N ha⁻¹ in cowpea, 71–74 kg N ha⁻¹ in green gram and 125–143 kg N ha⁻¹ in black gram. In addition to legumes, symbiotic N contribution is also reported to benefit the cereal crops with a relative yield increase of 11%–353% in as maize, rice, wheat and sorghum. Rhizobia can be indisputably used as inoculants for enhanced N fixation as studies have demonstrated their predominance in nodules for 5–15 years after initial inoculation. Such studies confirm that they are effective colonizers persisting in soil for many years even in the absence of their host.

Besides nitrogen, phosphorus (P) is an important plant growth limiting nutrient existing in both inorganic (bound, fixed, or labile) and organic (bound) forms in soil. Multiple factors limit their availability for plant growth. Soil microbes like *R. leguminosarum*, *R. meliloti*, *M. mediterraneum*, *Bradyrhizobium sp.* and *B. japonicum* are reported to help in P release to the plants. Organic acids secreted by such bacteria acts on inorganic phosphorous. For instance, 2-ketogluconic acid production with a phosphate-solubilizing ability has been identified in *R. leguminosarum* and *R. meliloti*. Importance of this P solubilizing capacity in enhancing plant growth by *M. mediterraneum* has been established in chickpea and barley plants.

Siderophores are water soluble and are of two types viz. extracellular and intracellular and forms stable complex with heavy metals such as Al, Cd, Cu etc. Rhizobial species, such as *R. meliloti*, *R. tropici*, *R. leguminosarum* bv. *viciae*, *R. leguminosarum* bv. *trifolii*, *R. leguminosarum* bv. *phaseoli*, *S. meliloti* and *Bradyrhizobium sp.* are known to produce siderophores.

Phytohormones are the substances stimulating plant growth at lower/equal to micromolar concentrations which include indole-3-acetic (IAA) acid (auxin), cytokinins, gibberellins and abscisic acid. IAA is the primary phytohormone which accelerates plant growth and development by improving root/shoot growth and seedling vigor. 80% of bacteria isolated from the rhizosphere can produce IAA with the salient ones being *A. caulinodans*, *B. japonicum*, *B. elkanii*, *M. loti*, *R. japonicum*, *R. leguminosarum*, *R. lupine*, *R. meliloti*, *R. phaseoli*, *R. trifolii* and *Sinorhizobium sp.* 60-fold increase in IAA was observed in the nodules of vetch roots, on inoculation of *R. leguminosarum* bv. *viciae*. Another phytohormone cytokinin stimulates plant cell division and in some instances root development and root hair formation as well. 90% of rhizospheric microorganisms are capable of releasing cytokinins. *Rhizobium* strains are also reported as the potent producers of cytokinins. Gibberellins, plant hormone responsible for stem elongation and leaf expansion is shown to be produced by *Rhizobium* and *S. meliloti* while *Rhizobium sp.* and *B. japonicum* had been reported to produce abscisic acid.

Rhizobia also has the ability to uptake ACC thereby converting it into α -ketobutyrate and NH₃ which is used as carbon and nitrogen source. On inoculation of rhizobia producing ACC deaminase, plant ethylene levels get lowered resulting in longer roots and providing relief from stresses such as heavy metals, pathogens, drought, radiation and salinity. Rhizobial strains like *R. leguminosarum* bv. *viciae*, *R. japonicum*, *R. gallicum*, *B. japonicum*, *B. elkanii*, *M. loti* and *S. meliloti* had been known to produce ACC deaminase.

Several rhizobial strains are reported to have biocontrol properties including competition for nutrients, production of antibiotics, siderophores and cell wall degrading enzymes including production of metabolites like HCN, phenazines, pyrrolnitrin,

viscoinamide and tensin. *R. leguminosarum* bv. *trifolii*, *R. leguminosarum* bv. *viciae*, *S. meliloti* and *B. japonicum* have been reported to secrete antibiotics and cell-wall degrading enzymes that can inhibit the phytopathogens.

Population Biology

The most basic issues in microbial ecology are to recognize the diversity and to enumerate the population under study. These are challenging objectives with all bacteria. With regard to rhizobia, one difficulty already mentioned is that rhizobia in the soil are in a dynamic genetic situation whereby they lose and pick up gene clusters that confer composite properties such as the one that we use to define them, the ability to incite nodules and fix nitrogen in association with legumes. Traditionally, soil rhizobia have been counted by using legume hosts as a means of selecting them from the notoriously diverse microbiota of the soil. Most probable numbers are calculated from the incidence of nodules arising from more and more dilute extracts of a particular sample of soil. This method is a reasonable measure of the most competitive rhizobia capable of nodulating the host that is used to trap them. It misses completely all those rhizobia that cannot do so, for example, rhizobia for other hosts and the aforementioned strains that have lost symbiotic capability. This is only one of many challenges in making absolute enumerations and enumerations relative to other bacteria (which themselves are subject to similar caveats). Therefore, the advent of new technologies, chiefly based on genetic probes, for identifying and enumerating bacteria in natural populations is revolutionizing the study of the ecology of rhizobia, just as it is of other bacteria. With these cautionary realities having been stated, it has been estimated through traditional sampling of soils that *Rhizobium*, *Sinorhizobium*, and *Bradyrhizobium* represent between 0.1% and 8% of the total population in bulk and rhizosphere soil. In view of the tremendous variety of bacteria that may inhabit the soil, even the lower of these numbers is significant. As might be expected, studies show that one of the most important factors determining the relative populations of rhizobia is whether a legume host has been cultivated in that soil. Generally, repeated cultivation of a particular legume will greatly enhance the populations of bacteria capable of nodulating it, relative to other rhizobia.

Therefore, rhizobia effectively compete with other bacteria in sustaining their soil populations. Also interesting in a basic sense, and very important to the inoculant industry, is that rhizobia of course compete with one another for the habitat of the legume nodule. In a given field setting, there are 'dominant' strains, strains that appear to inhabit the nodules of the particular host in higher numbers than other strains. An example is the so-called serogroup 123 of *B. japonicum* that competes well with inoculants and other indigenous strains for nodulation of soybean in the Midwestern region of the United States. The mechanisms involved in this important property are not yet elucidated. They are likely to be multiple and complex, involving not only innate differences in the early interactions with the host legume, but also coping with the particular and varying soil conditions, such as pH, viruses, antibiotics, predation, temperature, desiccation, and available nutrients.

Glossary

Biocontrol microorganisms Microorganisms that benefit the host plant by suppressing plant pathogenesis. They accomplish biocontrol by various mechanisms, for example, antibiosis, hyperparasitism, nutrient competition, and activation of induced systemic disease resistance in plants. Serves as an example indicating the benefits of enhanced plant growth due to PGPR bacteria (see below), or of microbial communities defeating plant pathogens.

Bioremediation Natural degradation of xenobiotic compounds that pollute the environment. In terrestrial habitats, bioremediation is enhanced in plant rhizospheres due to the increased availability of nutrients in this environment that fuel the microbial metabolism required to degrade the pollutant.

CMEIAS Center for Microbial Ecology Image Analysis System; advanced software tools of bioimage informatics designed to strengthen microscopy-based methods for understanding microbial ecology, especially the microbial colonization of roots.

Endophytes Microorganisms living within healthy plants, especially abundant in the interior of mature roots grown in soil but several can also colonize aerial parts.

Exudates Various root-derived, low molecular weight, carbon-rich, and energy-yielding compounds, for example, organic acids, released from the plant root into the surrounding environment where they enrich and are catabolized by microorganisms.

Plant growth-promotive rhizobacteria (PGPR) Root-colonizing bacteria that benefit the growth and development of the host plant by various means, including nitrogen fixation, phosphate solubilization, phytohormone production that enhances root development and increases nutrient acquisition efficiency, biological control of soil-borne root-infecting pathogens, and induction of systemic plant disease resistance.

Rhizoplane The root epidermal surface at the plant–soil interface that is colonized by rhizosphere microorganisms.

Rhizosphere The region of soil immediately influenced by living roots, where exudates are deposited to stimulate microbial metabolism and productivity.

Abbreviations

AHLs	N-acyl homoserine lactone
CLSM	Confocal laser scanning microscopy
CMEIAS	Center for Microbial Ecology Image Analysis System
Gfp	Green fluorescent protein
HHPR	Human health-promoting rhizobacteria
IFM	Immunofluorescence microscopy
PGPR	Plant growth-promoting rhizobacteria
Rfp	Red fluorescent protein
R:S	Rhizosphere-to-soil ratio
SIP	Stable isotope probing

Defining Statement

The rhizosphere includes living plant roots and closely associated soil where deposited exudates stimulate microbial activities that significantly influence plant health and disease, and therefore is immensely important to terrestrial life on Earth. Activities within the rhizosphere impact on the equilibria of microbial immobilization and mineralization of plant nutrients that

[☆]*Change History:* August 2016. Frank B. Dazzo improved the text throughout the article; updated Fig. 2; and added data for Table 2, new references, and a list of Relevant Websites. A. Garoutte introduced a description of metatranscriptomics applied to rhizosphere research. May 2018. Anton Hartmann revised and updated portions of the article and added new references accordingly.

profoundly influence their cycling in soil, on plant growth and development, and on the susceptibility and resistance of plants to infectious diseases.

Historical Aspects of the Rhizosphere Concept

In 1904, Lorenz Hiltner coined the term “rhizosphere”, which he defined as the “soil compartment influenced by the root”. His thorough investigations showed that microorganisms heavily populate the soil surrounding plant roots, the plant surface and root interior. Root exudates support different microbial communities, and plant roots and their associated microflora can significantly influence each other’s activity and development. For instance, some of the microbes whose abundance and metabolic activity are stimulated in the rhizosphere are welcomed friends that can significantly promote the growth of the plant, whereas other uninvited guests are foes that capitalize on root exudates by proliferating in the rhizosphere where they harm the plant. Hiltner also reported clear microscopic evidences that healthy plant roots are colonized inside by bacterial cells. These endophytic bacteria had been first reported by the French botanist Galippe in 1887. In analogy to the “mycorrhiza” (fungal root symbionts), he called the root associated bacterial community “bacteriorhiza”. In 1891, Hiltner and his academic teacher F. Nobbe had launched the first patent of an effective rhizobial inoculant for legumes, which they named “nitragin”. Hiltner’s key findings, as summarized by Hartmann et al. catalyzed the beginning of a greater than century-old era of rhizosphere microbiological research that enjoys an abundance of basic and applied scientific discoveries. Currently, plants and their associated microbes are recognized as metaorganisms or holobionts, in which roots and the rhizosphere are important organs to contact and explore the vast microbial reservoir of soils.

General Characteristics of the Rhizosphere

Nutrient Enrichment in the Rhizosphere

Most root-free soils are nutritionally oligotrophic, and therefore ~80% of the microbes there by and large persist on a low-calorie diet, with the major limitation to their productivity being the low availability of energy-yielding organic nutrients. The rhizosphere includes the root and surrounding soil influenced by living plant roots (Fig. 1). Rhizosphere soil contains significantly increased supplies of organic matter that include readily utilizable organic nutrients as soluble exudates, and also polymeric carbon substances like polysaccharides and mucus substances on the root surface. This nutritional enrichment results in more intense microbial metabolism and productivity in the rhizosphere than what is supported in bulk soil, with accompanying changes in respiration, gas exchange, nutrient and moisture availability. Plant roots can also be colonized by symbiotic fungi forming ecto- and endomycorrhizal structures. The “mycorrhizosphere” is also colonized by diverse bacterial communities – a part of it has mycorrhizal helper functions.

Measurements of the Rhizosphere Effect

Early studies on the microbial ecology of the rhizosphere measured the degree of enrichment with respect to culturable rhizosphere microorganisms and the various environmental factors that influence it. A rhizosphere-to-soil ratio (R:S) was introduced to define the magnitude of the rhizosphere effect. This metric is typically computed as the parameter (e.g., density or activity of microbes) measured in rhizosphere soil divided by the value of the same metric in nearby nonrhizosphere control soil uninfluenced by roots. Thus, root-associated enrichments would produce R:S values >1, whereas those parameters that are unaffected or suppressed by roots would have R:S values equal to or less than 1, respectively. Typical R:S values based on microbial culturability vary among plant species, soil horizon, and microbial physiological groupings, as indicated in Table 1. In contrast to A horizon soils enriched with organic matter, B horizon soils containing very low organic matter content supports microbial activity with typically higher R:S ratios. In addition, low carbon soils like dunes or desert sandy soils have extremely high R:S ratios. High R:S ratios for protozoa reflect the increased abundance of their bacterial prey in this environment, and this higher bacteriovore activity accounts for a significant microbial loop that accelerates mineral nutrient cycling in the rhizosphere, thereby benefiting plant nutrition overall. A high R:S ratio of the denitrifier functional guild reflects this environment’s increased abundance of organic matter, lower pO₂

Fig. 1 Areas of plants colonized by microorganisms.

Table 1 Classical analysis data of the rhizosphere effect based on measurements of the influence of various plant species on the major microbial groups and functional guilds in rhizosphere soil^a

Microbial group or functional guild	Plant	Rhizosphere effect (R:S ratio) ^b
Bacteria	Red clover	24
Bacteria	Maize	3
Bacteria	Yellow birch, A horizon	15.1
Bacteria	Yellow birch, B horizon	57.8
Bacteria	Mangles	120
Protozoa	Mangles	3–23
Filamentous fungi	Wheat	6
Microalgae	Wheat	11
Cellulose-degrading bacteria	Wheat	5
Nitrifying bacteria	Wheat	1
Ammonifying bacteria	Wheat	50–125
Denitrifying bacteria	Wheat	90–1260

^aData are based on viable plate counts and derived from studies by Katznelson and coworkers.

^bThe R:S is the metric that defines the magnitude of the rhizosphere effect on its associated microbial community and is typically computed as the value of the parameter measured (e.g., microbial abundance, diversity, or activity) in rhizosphere soil divided by its corresponding value in nearby nonrhizosphere control soil. Thus, root-associated enhancements would produce R:S values >1, whereas those parameters that are unaffected or suppressed by roots would have R:S values equal to or less than 1, respectively.

due to the higher biological oxygen demand that accompanies degradation of organic matter and depletion of oxygen by microbial aerobic respiration, and the utilization of NO_3^- (if available) as the microbes' second best choice of alternate electron acceptor to support ATP-yielding respiration.

Evidence for a lower in situ pO_2 in the rhizosphere is supported by manometric measurements of total oxygen uptake in rhizosphere versus nonrhizosphere soil that produce R:S values ranging from 2 to 5, depending on the plant species. This increased indicator of aerobic respiration reflects the combined influence of readily oxidizable nutrient enrichments and the large community of metabolically active, O_2 -utilizing rhizosphere microorganisms.

Microbial Diversity and Nutritional Requirements in the Rhizosphere

Derived from neighboring soil, the rhizosphere harbors a vast diversity of prokaryotic and eukaryotic microorganisms, including bacteria, archaea, fungi, protozoa, green algae and diatoms as well as viruses of these host organisms. Most studies of rhizosphere microbial ecology focus on the bacterial and fungal (especially mycorrhizal) components, although some new research focuses on the involvement of archaea in soil, the occurrence and functionality of viral populations, pathogenic repression, nitrogen transformations (including nitrogen fixation, denitrification and ammonium oxidation), and the association of green algae with desert plants. Early studies indicated that the large diversity of culturable bacteria in the rhizosphere is typically dominated by Gram-negative, rod-shaped pseudomonads with nutritional requirements satisfied by one or more amino acids or organic acids. In contrast, the large diversity of culturable bacteria in nonrhizosphere bulk soil is typically dominated by Gram-positive, *Arthrobacter*-like pleomorphic forms and *Acidobacteria* with complex nutritional requirements satisfied by hot-water extractable nutrients in soil organic matter, but not by simple sugars, amino acids, or organic acids. Using the metagenomics approach with high throughput sequencing and informatics tools (see below), nearly the whole diversity of microbial communities is readily accessible, which allows differentiating much better between rhizosphere microbial communities of different plants in different soil environments.

Culturability and Fitness Characteristics of Rhizosphere Microbes

Populations of rhizosphere bacteria increase rapidly and are most competitive when organic nutrient inputs are high (as in the rhizosphere), but decline dramatically when they become limiting. These characteristics are typical of zymogenous, copiotrophic R strategists. In contrast, typical nonrhizosphere soil bacteria are classified as autochthonous, oligotrophic K strategists that exhibit the opposite behavior of successful competition and perseverance with low mortality rates in habitats with low nutrient concentrations (as in bulk soil) because of their superior high-affinity nutrient transport systems, ability to convert soil organic matter into microbial biomass and to synthesize/utilize storage reserve polymers that enable extended starvation survival in the absence of abundant external nutrient apportionments.

The zymogenous nature of typical rhizosphere microorganisms like *Pseudomonas* is also reflected in the significantly higher proportion of the resident community that can be cultured in the laboratory. Interestingly, 40%–70% of the total rhizosphere bacterial community is culturable, whereas only 0.1%–1.0% of the total bacterial community in nonrhizosphere bulk soil is typically culturable. Thus, this "plate count anomaly" poses a more severe challenge when attempting to culture bacteria from bulk soil compared to rhizosphere soil, and therefore the rhizosphere represents an accessible reservoir of culturable microorganisms with high phylogenetic and metabolic diversity. This significantly higher proportion of the rhizosphere community being culturable

likely reflects microorganisms sampled while in a more metabolically active physiological state, that is, when they have faster growth rates and less stringent nutritional and physiological growth requirements that can be satisfied by culture media formulations and cultivation conditions in the laboratory.

Studies using mutant analysis of rhizobacterial *Pseudomonas* and *Bacillus* spp. indicate that their high competence in ability to colonize tomato rhizospheres involves several physiological systems, including chemotaxis, pili-mediated twitching motility, lipopolysaccharide O-antigen biosynthesis, metabolism of vitamins/nucleotides/organic acids, cell autoaggregation, diverse nutrient uptake and utilization pathways, protein secretion, high affinity iron siderophore production and various antibiotic synthesis, lipopeptides. Other studies using *Pantoea agglomerans* and *Rhizobium leguminosarum* have added production of acidic exopolysaccharides and cellulose microfibrils, in situ biofilm or microcolony formation, and cell surface adhesins to this list of important fitness determinants of bacterial competence in rhizosphere colonization.

Root Exudation and Rhizodeposition in the Rhizosphere

The high metabolic activity and productivity of the microbial community in the rhizosphere is mainly supported by carbon inputs from live roots that are delivered into that environment in various forms, including water-soluble compounds in root exudates, dead epidermal root cells, root cap cells, and mucilage polymers that slough off the root to lubricate its tip during its penetration and geotropic growth through soil.

Classic studies by Rovira and colleagues analyzed root exudates of plants grown “axenically” (without associated microorganisms). These studies identified various low molecular weight organic compounds including numerous sugars, amino acids, vitamins, organic acids, nucleotides, enzymes, and several phenolic compounds in root exudates. The spectrum and abundance of the excreted plant metabolites varied among different species and ages of plants, and this information helped to solidify the concept that the rhizosphere effect is primarily a consequence of increased microbial metabolic/physiological activity made possible by nutrient enrichments through root exudation of carbon-rich and energy-yielding compounds into the soil environment surrounding roots.

All of the carbon lost from plant roots is termed “rhizodeposition,” and in addition to the above types, includes respiratory CO₂ and other organic volatiles like ethylene. Much effort has been expended to measure rhizodeposition and identify factors that influence its magnitude. Its values range widely in different experimental systems, reaching as high as 50% of net primary production in some ecosystems. For optimized lab studies, typically, ¹⁴CO₂ is provided to the photosynthetically active above-ground plant system, and the amount of ¹⁴C-labeled photosynthates exuded from roots is measured. These studies show that rhizodeposits of amino acids and carbohydrates are higher when roots are grown in a porous matrix of soil particles (rather than in hydroponics), and the proportion of ¹⁴C-labeled rhizodeposits is significantly higher (18%–25% vs. 4%–10%) when plant roots are grown in unsterilized soil (with an active rhizosphere microbial community) rather than in sterilized soil. Other studies show that extracellular metabolites of rhizosphere-competent microorganisms like *Pseudomonas* spp. and *Fusarium oxysporum* can significantly increase carbon exudation from plant roots. Important implications of these rhizodeposition studies are that plants release significant amounts of newly fixed photosynthates through their roots without assimilating them into plant biomass, and that rhizosphere microorganisms can significantly increase – even double – the amount of fixed carbon lost through root exudation. Plants are even able to respond to pathogen uptake with the exudation of specific metabolites controlling the attacking pathogen by a disease-induced microbial assemblance, as summarized by Berendsen et al. In general, there are ample evidences that plants drive the selection of rhizosphere microbes from the soil microbial community.

Rhizodeposition does not occur uniformly along the plant root. Various approaches have been used to locate the major sites of nutrient exudation, including ninhydrin staining of filter paper imprints of growing roots to locate concentrated sites of amino acid exudation, localized chemotropism of amino acid-requiring auxotrophs of *Neurospora crassa* fungi on roots, and localization of genetically engineered LacZ or Lux reporter strains of rhizobacteria inoculated on plant roots. All of these methods revealed that the major sites of root exudation are located in the elongation region of the root just above the meristem and quiescent center, and at the base of emerged lateral root branches.

The Volume and Spatial Scale of the Rhizosphere

The volume of the rhizosphere that extends out from the root cylinder into surrounding soil is a dynamic function of the rate of plant rhizodeposition, the diffusion of nutrients influenced by their size/solubility/charge within the soil matrix, absorption to and mechanical impedance of the soil matrix, and the extent of uptake and utilization of the rhizodeposits by the rhizosphere community. The radial distance of the rhizosphere has been examined by measuring the concentration gradient of carbon rhizodeposits and the density of colony-forming units and individual bacterial cells in soil sampled at various distances from the root surface. These studies indicate that the rhizosphere effect is typically most intense at the root surface (called the “rhizoplane”) and its gradient extends outward a few millimeters to little more than a centimeter within the soil. Factors that influence this gradient of intensity and spatial scale of the rhizosphere effect include the species and growth stage of the plant, its root architecture and density, the light intensity and duration of the photoperiod affecting the synthesis of photosynthates, the texture/depth/fertility/and moisture status of the soil, and the types/abundance/and activities of the microbes, just to name a few. Fig. 2 schematically illustrates how root architecture influences the volume of different plant rhizospheres, indicating that its volume is much larger when produced by plant root systems that are fibrous and highly branched.

Fig. 2 Schematic drawing illustrating how the root architecture influences the volume of the rhizosphere.

Rhizospheres of neighboring plants can occupy significant volumes that even overlap when their branched root densities are sufficiently high. For example, 30%–40% of the top 10 cm of A horizon soil lies within 1 mm of a wheat root at its dough stage in development. Considering the high root density of lawn turfgrass, all the soil to depths of its longest roots is rhizosphere.

Direct Microscopy of Microbial Colonization of Roots

Early Microscopy Studies

Starkey, Krasilnikov, Rovira, Bowen, and Foster conducted pioneering studies that utilized microscopy to examine the rhizosphere effect directly. A clever way to examine the microbes inhabiting this habitat *in situ* utilized a seedling contact slide modification of the Rossi–Cholodny buried slide technique (Fig. 3). Also, roots grown in soil were gently removed, washed, processed and examined by brightfield light microscopy, and by transmission/scanning electron microscopy to examine the rhizoplane microorganisms. These studies verified earlier findings obtained by cultivation methods, showing the increased abundance of microbes in soil surrounding roots, their cooperative growth into microcolonies, ultrastructural details of the rhizosphere soil fabric, preliminary descriptions of the spatial distributions of the microbes on the rhizoplane, direct demonstration of a mucilage layer on the root surface that sometimes embeds microorganisms within it, bacteria surrounded by abundant fibrillar capsules (made during carbon excess) whose periphery is covered with a particulate layer of protective clay envelopes, increased abundance of bacterial colonization in grooves between adjacent epidermal cells where exudation is predictably elevated, local sites of eroded epidermal walls allowing microbial penetration, and direct evidence of biological control via “hyperparasitism” (beneficial microorganisms directly attacking and killing other microbial pathogens of plants). Examination of root cross sections of soil-grown plants showed that their internal root cortex naturally supports large populations of microorganisms without the plant expressing symptoms of disease. This benign (often beneficial) associated community of microorganisms inside the root is termed the “endorhizosphere,” and the organisms are called “endophytes” or “internal root colonists.”

Fig. 4 is a color fluorescence micrograph of a microbial assemblage within rhizosphere soil surrounding a white clover seedling root. This image acquired by conventional epifluorescence microscopy shows the clustered distribution of the morphologically diverse unicellular and filamentous bacteria in close association with reddish-brown autofluorescent particles of organic matter, but its image quality is reduced because many foreground objects lie outside its plane of focus.

Fig. 3 (a) Schematic diagram illustrating the experimental design of the seedling contact slide method to examine the rhizosphere effect by direct microscopy. (b) Direct microscopy of the abundant, localized colonization of seedling root tissue by rhizosphere microorganisms on a seedling contact slide. The sample was stained with aniline blue and photographed using brightfield light microscopy.

Fig. 4 Color fluorescence micrograph of a microbial assemblage within rhizosphere soil surrounding a white clover seedling root. The sample was treated with acridine orange (a vital nucleic acid stain), then rinsed with sodium pyrophosphate solution and examined by conventional epifluorescence microscopy.

Improvements in Direct Microscopy Using CLSM

The most significant advancement in the use of fluorescence microscopy to examine root-associated microbes was the development of confocal laser scanning microscopy (CLSM). The confocal imaging system has an optical design utilizing pinhole apertures at the laser light source and at the detection of the object's image, thus eliminating the stray and out-of-focus light that interferes with the formation of the object's image. This ability to use only signals from the focused plane eliminates a major limitation of the conventional fluorescence microscope when examining plant tissue, soil particles, and organic debris that emits a significant amount of objectionable background autofluorescence and/or absorbs the fluorescent dye itself. Because the light from outside of the plane of focus is not included when the confocal image is formed, the 2-D (x,y) image becomes an accurate optodigital thin section with a thickness that can approach the theoretical 0.2 μm resolution of the light microscope. Also, by digitizing a sequential series of 2-D images acquired at incremental depths while focusing through the specimen in the third (z) dimension (called the "Z series"), an all-inclusive flattened stack or a 3-D reconstructed digital image can be produced, optimally rotated, and quantitatively analyzed. Dazzo and Hartmann independently and simultaneously first reported the successful use and benefits of CLSM to examine the colonization of roots by the associated bioactive microbial community (Fig. 5(a) and (b)), or by a specific inoculated organism using a homologous fluorescent antibody.

Fig. 5 Use of confocal laser scanning microscopy (CLSM) to detect rhizoplane microorganisms colonized on roots grown in soil. White clover seedlings were grown in soil for 2 days, cleared free of rhizosphere soil using optimized methods described in the book COST 631: Handbook of Methods in Rhizosphere Research, then stained with acridine orange vital dye, washed, mounted with an anti-fading reagent (e.g., Vectashield, Citifluor) to inhibit photobleaching of fluorescent dyes, and examined by epifluorescence CLSM. The image (a) historically introduced CLSM technology to visualize bioactive rhizosphere microorganisms in situ, and the image (b) shows direct evidence of bacterial population growth and formation of a microcolony biofilm (arrow) developed on the rhizoplane. Reproduced from Dazzo, F.B., 2004. Applications of quantitative microscopy in studies of plant surface microbiology. In: Varma, A., Abbott, L., Werner, D., Hampp, R. (Eds.), Plant Surface Microbiology. Germany: Springer-Verlag, pp. 503–550, with permission from Springer-Verlag.

Fig. 6 Binary montage image depicting the spatial distribution of microorganisms colonized on the rhizoplane of a white clover seedling after 2 days of growth in soil. Note the discontinuous spatial density of microcolonies that is greater on older regions of the root.

By utilizing these CLSM technologies, one can map the distribution of rhizoplane microbial communities that, when analyzed, can reveal their colonization behavior on seedling roots grown in soil. Fig. 6 shows a typical density map, illustrating that the spatial distribution of microorganisms on the rhizoplane is discontinuous and spatially discrete, being almost completely devoid of microbes at the root tip while actively growing in soil, and individual cells just above the root tip, some of which eventually develop into microcolonies further up older portions of the root. Generally, microbes reach population densities that cover not more than ~20% of the rhizoplane substratum of roots that are actively growing in soil. During early stages of microbial colonization, discrete regions of the rhizoplane environment are favorable for growth of individual microbial cells into localized microcolony biofilms with in situ population generation times as short as 2–3 h.

A Case Study: *Rhizobium* Colonization of Rice Roots

Rhizobium is the well-known nitrogen-fixing root nodule bacterial symbiont of legume plants. Interestingly, this soil microorganism also develops natural, invasive and sometimes beneficial endophytic associations with major cereal crops like rice, corn and wheat. This alternate ecological niche of *Rhizobium* can be exploited in sustainable agriculture in the form of efficient biofertilizers that are inoculated on the cereal plant host at planting and can significantly promote its growth, while reducing its need for chemical fertilizer applications to achieve maximum grain yield. Figs. 7 and 8 illustrate stages of the colonization and endophytic infection of rice roots by *Rhizobium* using CLSM, scanning and transmission electron microscopy, respectively. The dynamic infection process of this association begins with their epiphytic colonization of the rhizoplane (especially collars surrounding the base of lateral roots and at junctions between epidermal cells), then localized pit erosion of root cell walls mediated by *Rhizobium* cell-bound cellulases, portals of crack entry into void spaces created by natural wounds at lateral root emergence and fissures between epidermal cells, endophytic colonization of dead cortical cells within the root interior, and ascending migration of *Rhizobium* cells into above-ground tissues.

CMEIAS Image Analysis of Microbial Colonization Behavior

Computer-assisted microscopy and digital image analysis can significantly enhance the quantitative assessment of microbial colonization on roots by allowing one to extract, store, retrieve, and electronically transmit numerical information regarding selected and pertinent image features. Image analysis of bacterial cells can provide useful information on the morphological diversity, local abundance, and patterns of spatial distribution reflecting their nutritional apportionment, allometric relationships of metabolic ecophysiology, and colonization behavior involving cell–cell interactions between microbial community members. A system of computer-assisted microscopy has been developed by the Center for Microbial Ecology at Michigan State University to assist in such assessments. The Center for Microbial Ecology Image Analysis System (CMEIAS; see “Relevant Websites section”) is a semiautomated software analysis tool of bioimage informatics that uses computer vision and pattern recognition techniques in conjunction with microscopy to extract quantitative information from digital images of microorganisms, allowing culture-independent, object analysis and classification of individual cells, microbial populations and complex microbial communities. Quantitative in situ studies of microbial biogeography on rhizoplanes are greatly facilitated using this bioimage informatics software, especially to define the real world spatial scale of quorum sensing at single-cell resolution, niche overlap and competition among populations, and the landscape ecology of root colonization by microcolony biofilm communities.

As an example of using computer-assisted microscopy to examine the autecological biogeography of specific organisms colonized on root surfaces, CMEIAS image analysis was performed on Fig. 9 containing 136 fluorescent antibody-labeled bacterial cells of *Rhizobium leguminosarum* bv. *trifolii* on the white clover rhizoplane. In approximately 400 ms of computing time, CMEIAS extracted several measurement features from these foreground objects, and reported the data (Table 2) that defined their sizes, local spatial abundance and pattern of distribution providing insights on their colonization behavior and ecophysiology on the root surface.

Of particular ecological importance are the image analysis data needed to perform nearest neighbor distance-based and quadrat-lattice based spatial pattern analyzes, and geostatistical analyzes on autocorrelated spatial interactions among the bacteria. These attributes define indices of spatial association, dispersion and mathematical modeling that predict bacterial colonization behavior in situ. The spatial randomness index, computed from the image area, average and standard deviations of the first nearest neighbor distances (Table 2), provides quantitative assessments (values <1.0) indicating that the bacteria in this Fig. 9 landscape image exhibit a clustered pattern of spatial distribution. Other analyzes of spatial aggregation are also included because the use of only a single index may be misleading. This indication of cells having an aggregated pattern on the root surface is confirmed quantitatively by five other plot-based spatial distribution indices (variance:mean ratio, Morista’s dispersion index, negative binomial K, Lloyd’s mean crowding index, and Lloyd’s patchiness index; Table 2) computed from the CMEIAS data. Geostatistical analysis shows that

Fig. 7 Epifluorescence confocal laser scanning microscopy showing colonization of the rhizoplane and internal root structures of rice by rhizobia. (a) and (b) Preferential colonization of a dense collar of rhizoplane rhizobia (arrows) surrounding the base of emerged lateral roots. (c) and (d) Endophytic rhizobial colonization of underlying, lysed root cortical cells and the vascular cylinder of rice roots. Rhizobia are stained with acridine orange in (a) and (c) and are an engineered reporter expressing the green fluorescent protein in (b) and (d). Images (a) and (c) are reproduced from Reddy, P.M., Ladha, J.K., So, R., et al., 1997. Images (b) and (d) are reproduced from Chi, F., Shen, S.H., Cheng, H.P., et al., 2005. Ascending migration of endophytic rhizobia from roots to leaves inside rice plants and assessment of their benefits to the growth physiology of rice. *Applied and Environmental Microbiology* 71, 7271–7278, with permission from the American Society for Microbiology.

this clustered behavior is spatially autocorrelated, with an intensity of influence that extends from individual bacterial cells out to an effective radial distance sufficiently large enough to include all their neighboring cells in this image of the rhizoplane landscape. Aggregated spatial patterns of distribution arise from positive, cooperative colonization behaviors of the bacteria *in situ*, benefitting each other's ability to actively growing into microcolony biofilms on the root surface. This occurs frequently at fissure grooves between adjacent epidermal cells just below and within the root hair region where localized root exudation is high. This category of colonization behavior differs from a random colonization pattern (occurs infrequently on roots when there are no spatially explicit events affecting colonization), and is diametrically different from a uniform spatial pattern of colonization that arises from negative conflicting cell–cell interactions during colonization, resulting in their maximally dispersed, self-avoiding distributions.

Further CMEIAS analysis shows that this spatially structured distribution among cells also exhibits fractal geometry, which reflects complex (often anisotropic) patterns and ecophysiological processes occurring within natural microbial landscapes, including the scale-dependent heterogeneities of their biomass distribution and cell–cell interactions in the biofilm architecture, all driven by the benefits that populations gain by their optimal spatial positioning to maximize their apportionment, accessibility and efficiency in utilization of allocated nutrient resources *in situ* within their local environment.

This clustered colonization strategy is further indicated by the multimodal (rather than normal) frequency distribution of the first and second nearest neighbor distances (Fig. 10(a)), and by the clustered abundance of short separation distances between individual cells revealed in the 2-D scatterplot of the first versus second nearest neighbor distance (Fig. 10(b)).

Microscopy of Genetically Marked Bacteria on the Rhizoplane

Several approaches of microscopy can be used to detect and measure colonization of the rhizosphere and/or rhizoplane by specific microbes. For instance, immunofluorescence microscopy (IFM) can be used to track inoculant strains of bacteria in the environment if strain-specific antibodies are available (e.g., Fig. 9). However, chemical inhibiting factors in soil and nonspecific absorption of the fluorescent antibody by the root can interfere with the IFM approach, and gelatin pretreatment of samples can help to suppress these problems. Alternative approaches using genetic engineering have also been developed to avoid such problems. Genetic markers encoding fluorescent proteins are inserted into their genome, which when expressed can be excited by light of specific wavelengths to make the cell autofluorescence. Commonly used genetic markers encode for a green fluorescent protein (Gfp) and red fluorescent protein (Rfp). Such techniques have been applied to study the distribution of bacterial populations colonized on roots (Fig. 11(a)). By using different markers and specific fluorescence optics, one can track root colonization by multiple bacterial populations in the same environment (Fig. 11(b)).

Two major concerns arise when applying this autofluorescent genetic marker approach to study bacterial colonization in situ. One is whether the metabolic burden of added biosynthesis to constitutively produce the autofluorescent protein influences the colonization behavior of the recombinant strain in ways that differ from its parental wild-type strain. The other is whether the recombinant cell stably maintains the genetic marker during its population growth within the environment. Such markers were originally introduced into the organism using plasmid constructs to ensure fast adaptations in their environment. But in this case, the antibiotic whose resistance is conferred by the plasmid must be present within the environment in order to impose the selective pressure needed to maintain the plasmid inside the bacteria and its replication in succeeding generations. Such selection pressure may severely disturb other members of its associated microbial community in the rhizosphere environment. Nowadays,

Table 2 CMEIAS image analysis of the abundance and spatial distribution of immunofluorescent bacteria on the white clover root epidermis shown in the image of Fig. 9

Spatial ecology parameter	Value obtained
Image area analyzed	10,434 μm^2
Bacterial cell count	136
% Rhizoplane substratum coverage	2.7%
Total microbial biovolume	259.0 μm^3
Total microbial biomass carbon	51.8 μg
Total microbial biosurface area	1126.6 μm^2
Spatial density	13,034 cells mm^{-2}
Fractal dimension Index	1.724
1st nearest neighbor distance (mean $\pm$ SD)	3.9 $\pm$ 2.4 μm
2nd nearest neighbor distance (mean $\pm$ SD)	5.7 $\pm$ 2.9 μm
Spatial randomness index	0.880 (clustered)
Quadrat-based variance:mean ratio	1.796 (clustered)
Morista's dispersion index	1.996 (clustered)
Negative binomial K index	0.950 (clustered)
Lloyd's mean crowding index	1.595 (clustered)
Lloyd's patchiness index	1.995 (clustered)
Effective range autocorrelated cluster behavior	86.7 μm (includes all cells)

these autofluorescent genetic markers are stably inserted into the bacterial chromosome to ensure transfer to each subsequent generation without the need for selective pressure. If such a marker is connected to a specific gene of interest, it can be used to display gene expression activity as a reporter construct in situ as described next.

A Case Study: CMEIAS In Situ Analysis of Quorum Sensing by Rhizobacteria

Many bacteria modulate their colonization and occupation of ecological niches in natural environments like the rhizosphere using specific cell-to-cell-communication systems based on elaboration of low molecular weight, extracellular signal molecules that allow

the bacteria to perceive neighboring microbes while colonizing the habitat. The signal molecules are commonly oligopeptides for Gram-positive bacteria and *N*-acyl homoserine lactone (AHLs) for Gram-negative bacteria.

The cell-to-cell communication system for Gram-negative bacteria is better understood. Above threshold concentrations, AHLs activate expression of certain bacterial genes to occupy their ecological niches, for example, biofilm development, production of virulence factors or antibiotics, and persistence and viability on colonized host surfaces. AHL-mediated cell-to-cell cross-talk can also be effective across species borders within microbial communities and even between prokaryotes and their eukaryotic plant hosts. Since the bacterial traits activated by AHLs can be beneficial or harmful to hosts, identification of the attributes that govern cell-to-cell communication is very important and has major practical application in the design and implementation of synthetic antimicrobial strategies that expressly target microbial biofilms, plant–microbe interactions in soil, and in aquatic environments.

It is generally thought that high bacterial population densities are needed to exceed the threshold level of AHL concentrations required to activate genes and their physiological functions. Hence, this specific type of microbial communication has become known as “quorum sensing,” functioning primarily as sensors of high population density, thus optimizing the expression of functions that are most beneficial when simultaneously performed by dense populations. This prevailing view is commonly based on measurements of gene expression within populations in liquid suspension or when grown into large biofilms on artificial substrata (e.g., pellicle in unshaken broth cultural media or on plastic surfaces). During planktonic growth, dispersion and dilution of the signaling molecules are much faster and further than their diffusion rates within biofilm matrices. For instance, spatial patterns of population dispersion and active growth within discontinuous domains are major ecological determinants that govern microbial colonization of host surfaces, especially plants, and during early stages of biofilm development. One could theoretically predict that individual bacteria should benefit significantly if their sensory system is able to respond efficiently to small, local concentrations of the signal molecule since that would communicate information about competitive and/or cooperative activities by a few local neighbors before they grow to high population densities in the cell’s immediate microenvironment. Core principles of bacterial autoinducer systems have recently been summarized by Hense and Schuster, which provide the general theoretical basis for an evolutionary concept of auto-inducing quorum sensing systems.

The combined technologies of fluorescent reporter strain constructions, confocal microscopy, computer-assisted digital image analysis, and geostatistical modeling for single-cell resolution experiments have been used to examine the *in situ* spatial scale and local population size requirements for AHL-mediated cell-to-cell communication during bacterial colonization of roots. These studies showed that this type of cellular communication occurs in the rhizosphere and can be accomplished by individual bacterial cells that are separated from each other and from high population densities by long-range distances (Fig. 12(a)–(c)). Reporter rhizobacteria were able to conduct AHL-mediated cell-to-cell communication on roots with a minimum quorum of two cells (no requirements for high population density) and an *in situ* separation “calling distance” of up to 78 μm (equivalent to two people talking to each other while standing ~ 130 m apart!). Also, individual bacteria in small clusters (2–3 cells) communicated with each other when separated from dense populations by even longer distances. Thus, during colonization of plant roots, a single bacterium is able to produce sufficient AHL signal molecules to communicate with another single bacterial cell neighbor even when they are separated apart by long distances. Geostatistical modeling of local spatial densities predicts that *in situ* AHL-mediated cell-to-cell communication is governed more by the spatial proximity of cells within AHL gradients than by a quorum requirement of high population density (Fig. 12(c)).

Nucleic Acid-Based Technologies in Rhizosphere Studies

Ribosomal RNA Gene-Based Fingerprint Techniques

The discovery by Carl Woese in 1977 that the 16S ribosomal nucleic acid sequence can be used as identification criteria for microorganisms has revolutionized the characterization of microbial communities in environmental studies. Nowadays, many important and even cutting edge techniques use the combination of conservative and variable regions in the ribosomal gene sequence analysis to reveal taxonomic relations between organisms or similarities and differences in microbial community

Fig. 12 *In situ* distribution of individual fluorescent *Pseudomonas putida* cells conducting *N*-acyl homoserine lactone (AHL)-mediated cell-to-cell communication on tomato roots. (a) Confocal laser scanning micrograph of the root surface colonized by the red fluorescent IsoF source strain that produces AHLs, and the green fluorescent F117 (pKR-C12) reporter sensor strain activated by extracellular AHLs from neighboring source cells. Bar scales are indicated. (b) Posted locations of red AHL source and green AHL-sensor cells colonized on a root tip, and (c) continuous spatial interpolation map of the predicted gradients of AHL signal molecules in the same region of the root as indicated in (b), based on a CMEIAS-supported geostatistical block kriging analysis of the spatial distribution of each red (AHL-producing) cell weighted by its local spatial density (cells per quadrat subsample). Reproduced from Gantner, S., Schmid, M., Dürr, C., et al., 2006. *In situ* spatial scale of calling distances and population density-independent *N*-acyl homoserine lactone mediated communication by rhizobacteria colonized on plant roots. *Federation of European Microbiological Sciences Microbiology Ecology* 56, 188–194, with permission from FEMS Mic Ecol.

structure. Nucleic acid-based fingerprint techniques based on ribosomal gene sequence identification or detection methods allow one to track microbial community changes in environments quickly and without dependence on culturability. Refinements of this approach have made it more sensitive and specific, improving the detection of less-dominant bacteria, and recently, extending its use to include eukaryotic microorganisms within the same community sample. However, issues of their accuracy are raised since these techniques most often address only partial gene sequences, cannot guarantee that the total unbiased community is sampled (Gram-negatives are easier to lyse than Gram-positives or spores), are quantitatively affected by variations in genomic copy number among species, and will also include protected extracellular DNA sampled after cells have already naturally lysed.

In general, 16S rDNA gene analysis for prokaryotes and the corresponding 28S rDNA gene analysis for eukaryotes have revealed important taxonomic and environmental relationships of organisms in the rhizosphere. For instance, studies have documented the diversity of the nonculturable portion of the rhizosphere community and the strong impact environmental pressure plays in forming those microbial community structures. Consistent with early findings based on culturing techniques, gene-based sequencing studies especially targeting the 16S ribosomal RNA gene of prokaryotes indicate that the λ -proteobacteria group (of which pseudomonads are representative) embody, on average, ~35% of all bacterial cell clones isolated from rhizosphere samples of many plant species, and their numerical dominance in the rhizosphere of some plant species extends up to ~65% of all bacterial clones analyzed. Many microbial specialists occupying similar or identical ecological niches show closer relations to the rhizosphere community than to other members of their taxonomical orders. Such findings raise the question of the extent to which the taxonomical nomenclature and phylogeny related to the origin and evolution of microbial life can help to explain their real ecological functions in situ.

Array Technology – Functional Gene Arrays

Nanotechnologies have created the ability to differentiate thousands of gene sequences spotted on polymer-coated microchips, allowing for the simultaneous search for gene sequence similarity to environmentally extracted community DNA. Today, several biotechnology companies and research groups provide DNA chips for bacterial community identification. Functional gene arrays can potentially reveal the diversity of various known metabolic pathways potentially utilized by the rhizosphere microbial communities.

A Case Study: Functional Gene Arrays and rDNA Sequencing

The effects of global climate changes are influencing our daily life in an increasing scale. However, many changes in the biosphere remain unnoticed. The rhizosphere community of microbes contains potentially useful indicators of environmental changes, as they are responsive to changes in root exudations of plants, which can be perturbed by environmental changes affecting plant metabolism before variations in growth patterns are discerned. A combination of ribosomal DNA-based techniques and functional gene arrays has addressed this environmentally important question. Community analysis using terminal restriction fragment length polymorphism (a 16S ribosomal RNA-based fingerprint technique) revealed strong shifts in populations of certain microbial ribotypes in the rhizospheres of grassland plants treated with nitrogen fertilizer and CO₂ enrichments to simulate global climate changes as compared to nontreated controls. These population shifts resulting from the environmental perturbations were grass cultivar- and treatment-dependent, and revealed strong connections between the belowground microbial rhizosphere community and the aboveground plant host effects. Functional gene arrays further characterized the potential functional diversity in the microbial rhizosphere community. These results showed that different plants select and define their own functional rhizosphere communities, and that simulated climate changes have a strong impact on the diversity selected within those microbial communities, which in turn reflects on the physiological conditions of the plants. Indeed, despite their small spatial scale (from the human perspective), some rhizosphere processes impact on large-scale ecosystem responses to various drivers of global change, for example, rising atmospheric CO₂ concentration.

In related studies addressing impacts of global climate change, the successful colonization of the rhizosphere by species of *Burkholderia* and *Pseudomonas* spp. was significantly influenced by elevated CO₂, whereas species of *Bacillus* and actinomycetes (representing 2 groups of bacteria that are more dominant in bulk soil rather than rhizosphere) were not. These findings clearly indicate physiological differences between the lifestyles of rhizosphere-competent bacteria and other microbial groups not well adapted to that plant root-modified soil environment.

Use of Stable Isotope Probing to Examine Bioremediation Processes

Another modern technique used to characterize microbial community activity is the stable isotope probing (SIP) technology, which identifies and tracks microorganisms that are actively utilizing certain specialized compounds in the environment of interest. This method utilizes a labeled substrate containing heavy, stable isotopes (e.g., ¹³C, ¹⁵N, ³⁴S) harboring an additional neutron in their atomic structure. Microbial communities can metabolize this labeled substrate qualitatively (not necessarily quantitatively) the same way as unlabeled substrates, thereby incorporating the heavy labeled atoms into their DNA, RNA, or other metabolic products, which are then physically separated from the corresponding unlabeled polymer by density gradient ultracentrifugation. This technique allows one to study specific bacterial groups selected by the substrate they can utilize in situ.

Using this approach, one can introduce ¹³C-labeled xenobiotic compounds into the rhizosphere and identify organisms in that microbial community that are potentially important in degrading them, based on their utilization of the labeled substrate. This is an

important tool being used to identify organisms involved in bioremediation of environmental pollutants. In terrestrial habitats, bioremediation is enhanced in the rhizosphere due to the increased availability of nutrients that fuel the metabolism of microbial communities responsible for this activity. This SIP molecular tool provides the opportunity to explore more in-depth connections of the microbial communities involved in bioremediation and will likely reveal many more details about rhizosphere microbial ecology in the future.

Omics Technology Introduces New Opportunities in Rhizosphere Microbial Community Ecology Research

Advances in Next Generation high throughput sequencing technologies provide various new ways to investigate microbial communities in the rhizosphere without the use of culture-based techniques. Generally speaking, metagenomics is used to sequence DNA present in an environmental sample. Metagenomic techniques can be targeted to a specific gene of interest such as the 16S rDNA gene for taxonomic diversity analysis or another gene of interest such as *nifH* to identify variability within the portion of the community capable of nitrogen fixation. Metagenomic techniques can also be untargeted, often called “shotgun metagenomics,” where DNA is randomly sequenced from the environmental sample.

Gene-targeted and shotgun metagenomics suffer many of the same drawbacks as discussed above in “Ribosomal RNA Gene-Based Fingerprint Techniques.” Since shotgun metagenomics randomly sequences environmental DNA, the metabolic state of the microbes sampled is unknown and the sampled DNA can originate from dead or dormant microbes as well as living active microbes. Therefore metagenomics represents the functional potential of the microbial community. Additionally, short reads produced from illumina sequencing (currently the most popular sequencing platform) need to be computationally assembled and annotated to adequately determine the function of the DNA sequence. Sequence annotation is dependent upon matching the sequenced DNA fragment to already isolated and sequenced microbe genomes, therefore – omics technologies are still very much reliant on information already gained by culturing and laboratory based techniques. As a consequence, annotations of sequencing data are often incomplete, as sequences of some genes are not represented in the current databases. Sequences can also be annotated as “hypothetical protein” indicating there is no currently known function for the gene sequence. Nowadays, this latter category commonly represents 30%–50% of the bacterial genomes. Despite these drawbacks, metagenomes provide a wealth of information regarding the metabolic potential of the microbes in the environmental sample.

Another – omics method, called metatranscriptomics, specifically targets the sequencing of mRNA transcripts within an environmental sample. This technology removes one of the limitations of metagenomics since mRNA is only produced by active microbes and is short-lived within the cell, thereby offering a glimpse into the likely functional activities of the microbial community occurring at the time of sampling. Because of its instability, mRNA in meta-transcriptome samples will degrade quickly if not preserved via RNase-inhibiting solutions or frozen at -80°C . Technically challenging drawbacks of meta-transcriptomics include short read assembly and sequence annotation issues as described above, and the need to remove rRNA noise in the environmental sample as much as possible before sequencing since it can represent $\geq 90\%$ of the total extracted RNA.

A Case Study: Functional Gene Expression in the Rhizosphere

Yergeau et al. conducted a meta-transcriptomics study comparing the expression patterns of upregulated genes in bulk soil and willow rhizosphere soil. The study found that the rhizosphere samples were preferentially enriched for several categories of functional gene expressions related to plant–microbe interactions. *First*, the rhizosphere was enriched in expression of genes related to carbon uptake and utilization, especially the utilization of organic acids as a major component of root exudate, and also degradation of oligosaccharides and histidine. *Second*, the willow rhizosphere was enriched for upregulated expression of genes conferring antibiotic resistance, suggesting that active microbial resistances to inhibitory antibiotics present within the rhizosphere are important traits of stress fitness for successful colonization of that habitat. *Third*, the rhizosphere was enriched for upregulated expression of genes related to quorum sensing and biofilm formation. This indicates that microbial cells are communicating with one another while colonizing the rhizosphere. Finally, upregulated expression of many genes related to the nitrogen cycle were also enriched in the rhizosphere. These genes include ammonia monooxygenase, nitrogenase, and genes related to nitrate reduction, while bulk soil showed enrichment for genes related to denitrification. Those data show that the rhizosphere microbial communities are fixing nitrogen and converting it to a form that would be eventually usable by the plant, whereas the bulk soil microbial community is actively respiring nitrate as an anoxic alternate electron acceptor.

That study illustrates the power of meta-transcriptomics to identify upregulated genes involved in the colonization fitness of different microbial communities, the diversity of various known metabolic pathways currently being utilized by the rhizosphere communities, and the induction of stress resistance and signaling events based on their transcriptional activity. Importantly, that study confirmed many earlier laboratory-based findings of plant–microbe interactions conducted on microbial populations.

Importance of the Rhizosphere to Plant Growth

All of the physical, chemical, and biological factors or conditions of soil that influence the physiology of plant growth are expressed through the rhizosphere and its associated microbial communities. Thus, the rhizosphere is the business end of soil where major,

important soil–plant relationships occur. The outcomes of ecological interactions between rhizosphere microorganisms and higher plants embrace the full range of beneficial, neutral, or harmful associations, including commensalisms (one partner benefits), mutualisms (both partners benefit), amensalisms (one partner impedes the success of the other without being affected positively or negatively by the presence of the other), and pathogenic consequences (one partner benefits by harming the other). This section presents brief examples on negative and positive effects of such interactions.

Negative Effects of Microbes on Plants

Hiltner's view of the rhizosphere as an important habitat for microbes supporting plant growth and health as well as causing plant disease is still completely valid. Both prokaryotic and eukaryotic rhizosphere colonizers can harm their plant host. Some microorganisms successfully compete with plants for nutrients in soil, thereby immobilizing and limiting their availability sufficiently to inhibit plant growth. Some pathogens are necrotrophs that kill the plant hosts and then proliferate while degrading them (e.g., *Erwinia carotovora* degrades the plant cell wall structure to enter karat roots and causes a root rotting disease). Certain eukaryotic microorganisms are major pathogens of plants. For example, the filamentous oomycete, *Pythium* spp. causes a devastating root rot disease of significant agricultural importance. This pathogen invades the roots (particularly of seedlings) of many plant species, eventually killing the plant hosts by sealing off their nutrient and water transport systems for its own use. Such plant pathogens cause enormous economic damage to agricultural productions every year and therefore are of special interests in rhizosphere research. Understanding the mechanisms and characteristics of soil-borne, root-infecting plant pathogens is a major task in plant-associated research to prevent diseases and increase agricultural productivity.

Positive Effects of Microbes on Plants

Many microbial associations can significantly benefit plants, thereby attracting special interest in various fields of microbial ecology, especially in aspects of agricultural sustainability when it involves an important crop plant. Bacteria that benefit plant growth while colonizing their roots are called plant growth-promotive rhizobacteria (PGPR). PGPR use numerous direct and indirect mechanisms to promote plant growth. One common example is the ability of PGPR to supply the plant with essential nutrients that are otherwise limiting in soil. Examples include nitrogen-fixing bacteria (called diazotrophs) that reduce dinitrogen gas into ammonia and provide this form of fixed nitrogen to supplement the plant's nitrogen nutrition. The root nodule symbiosis between rhizobia and legumes is the classic example that uses this mechanism directly to promote the growth of the legume plant host, particularly when grown in soils limited in available combined nitrogen. Another example in this direct benefit category is the mycorrhizal fungus, which colonizes roots of 95% of all vascular plants. Their external hyphae extend from the mycorrhizal root out into the soil where they efficiently access nutrients, especially phosphorus, and transport them into the plant roots, thereby significantly impacting on plant mineral nutrition. The beneficial association of mycorrhizal fungi with plants also provides protection against soil-borne root infecting plant pathogens. Mycorrhizal helper bacteria (MHB) are colonizing the surface and even the interior of mycorrhizal hyphae and spores as summarized by Frey-Klett et al. In addition to mycorrhizal fungi, also members of the Sebaciniales order of fungal kingdom, like *Piriformospora indica*, readily colonize roots of many crop plants leading to increased growth, salt resistance and pathogen response as reviewed by Varma et al. Examples of the indirect benefit category involve increased bioavailability and enhanced acquisition of mineral nutrients include PGPR like *Azospirillum* or *Rhizobium* that stimulate elongation and branching of root growth (see section "A Case Study: *Rhizobium* Colonization of Rice Roots"). The resultant improved root architecture increases the plant's ability to access and exploit nutrient reserves in soil much more efficiently. Other examples using indirect mechanisms in this category include PGPR that solubilize soil complexes of inorganic and organic phosphates and iron that are otherwise largely insoluble in the rhizosphere and hence have limited availability to the plant. Crop plants can also benefit from the nitrogen fixation of root associated, mostly endophytic diazotrophs, like *Azoarcus* spp. in rice and *Gluconacetobacter diazotrophicus* and other diazotrophs in sugarcane.

Another major way that rhizosphere microorganisms improve plant health is mediated by their biocontrol against plant diseases. A direct benefit in this category includes the microbial stimulation of plant defense responses that induce systemic disease resistances in plants, enabling them to successfully defeat plant pathogenic attacks. Examples were revealed in studies using *Serratia liquefaciens* and *Rhizobium leguminosarum* that secrete bacterial quorum sensing molecules of the AHL-type inducing a systemic disease resistance reaction in tomato and *Arabidopsis* plants, respectively. In these cases, the induced systemic resistance system is primed leading to "immunization" of the plant that protects it against pathogen attack, as recently reviewed by Schikora et al. In the case of *Bacillus amyloliquefaciens*, the production of lipopeptides and other antibiotically active substances lead also to the induction of the plant's innate immune system resulting in improved defense against *Rhizoctonia solani*. Other beneficial microbe–plant interactions involve biocontrol mechanisms that act directly on the invasive pathogen itself rather than on the plant host. Examples include hyperparasitism whereby the PGPR aggressively attacks and kills the pathogen thereby reducing its inoculum potential, production of siderophores that restrict ferric (Fe^{3+}) availability and uptake by the pathogen, production of antimicrobial antibiotics that inhibit the pathogen's growth physiology thereby diminishing their virulence, and development of dense hyphal mantle sheaths of ectomycorrhizal filaments surrounding rootlets that impose physical barriers to block pathogen ingress.

Closing Remarks

The plant rhizosphere harbors a diverse reservoir of culturable and non-culturable microorganisms that can be exploited to benefit mankind. Many rhizosphere microbes benefit crop production, reducing the dependence on chemical fertilizers to achieve high productive yields. Others protect plants from the ravages of pathogens and the diseases they cause. Utilization of these beneficial examples is fully consistent with sustainable agriculture, where the goal is to utilize natural processes that promote the crop's output without irreparably damaging the natural resource base where the crop can be grown. Finally, the rhizosphere studies contribute to the greater understanding of plant microbiomes and plant holobionts. These metagenomic approaches are now even integrated with agronomic and environmental aspects into the holistic "phytobiome concept" of sustainable crop production.

Among the many recent discoveries in rhizosphere research is the ominous finding that certain potential human pathogenic microorganisms are also successful colonizers inhabiting this nutrient-enriched plant soil environment, and this ecology poses potential public health hazards for the people (both producers and consumers) who encounter them. Furthermore, there are also several examples reporting that some rhizosphere bacteria have probiotic abilities. However, care has to be taken, because it is quite challenging to clearly separate beneficial from possibly health threatening microbes. Much more experience and in depth genomic, in situ and functional studies of these organisms are necessary to reach the required safety level.

Acknowledgments

Portions of FBD's work described here were supported by the MSU Center for Microbial Ecology, the MSU-KBS Long-Term Ecological Research Program, the US-Egypt Science & Technology Development Fund, and Michigan AgBioResearch. The authors thank Youssef Yanni for collaborative studies of the *Rhizobium*-rice association, Yuxiang Jing for providing Fig. 7(b) and (d), Stephan Gantner for providing Figs. 11(a) and (b) and 12(a) and (b) and his contribution to earlier versions of this document, and to Jim Tiedje for helpful suggestions. In particular, AH greatly acknowledges the in-house funding of the special focus area "Molecular Interactions in the Rhizosphere" by the Helmholtz Zentrum München.

Glossary

Distributive Describing an enzyme that releases its substrate after each catalytic cycle.

Endoribonuclease Enzyme that cuts RNA internally.

Exoribonuclease Enzyme that chews RNA one nucleotide at a time from either the 5' or 3' end.

Homolog(ous) Having the same origin.

Intergenic region Sequence between two open reading frames.

Paralog(ous) Having the same origin, but in a single organism.

Processive Describing an enzyme capable of performing many catalytic cycles on the same molecule before releasing it.

Primary transcript Transcript first synthesized by RNA polymerase from point of transcription initiation to point of transcription termination.

Ribonuclease Enzyme that cuts or chews RNA.

RNA processing/maturation Conversion of precursor RNA to shorter, functional and usually more stable species by ribonucleases.

Shine-Dalgarno Bacterial ribosome binding site, complementary to 3' end of 16S rRNA, named after its discoverers.

Defining Statement

RNAs are synthesized as so-called primary transcripts extending from the point of transcription initiation by RNA polymerase to the point of transcription termination. In some cases, the primary transcript is the final functional molecule. In others, the primary transcript is “processed” to a shorter, more stable functional species by ribonucleases (RNases).

Introduction

While primary messenger RNA (mRNA) transcripts can typically be bound by ribosomes and used directly for translation, stable RNAs such as ribosomal RNAs (rRNAs) and transfer RNAs (tRNAs), are almost always processed from the primary transcript into shorter functional molecules. RNases remove sequences from the 5' or 3' end of stable RNA precursors, usually both. As we will see later, some mRNAs are also processed, that is, the major translated species found in the cell *in vivo* is not the primary transcript. The classic case is where an mRNA encodes more than one protein and is processed between cistrons. This can have important consequences for the stoichiometry of the different proteins produced from a single operon. At the outset, therefore, it is useful to distinguish the term “RNA processing” (or maturation), which is used to describe RNase-catalyzed events leading to the generation of a functional RNA, from “RNA degradation,” used to describe its decay. The first generally leads to an increase in RNA half-life relative to the primary transcript and, the second, to a decrease. In this article, we first describe some specific examples of mRNA processing and then focus for the remainder of the review on the maturation of stable RNAs. The vast majority of the work we describe will be from studies in *Escherichia coli* and *Bacillus subtilis*, the best-studied examples of the Gram-negative and Gram-positive bacteria, respectively. We emphasize some of the historical examples that served as paradigms for the different types of processing events. New examples are regularly discovered that give further weight to these pioneering studies.

The Players

Ribonucleases come in two flavors; endoribonucleases, which cut or cleave RNAs internally, and exoribonucleases, which remove nucleotides one at a time from either the 3' or 5' end. The former are typically symbolized as a pair of scissors, while exoribonucleases are usually represented by a “Pacman” symbol. Exoribonucleases can be either processive, remaining attached to the same RNA molecule for many rounds of catalysis, or distributive, releasing the substrate with each nucleotide removed. They can also be

[☆]*Change History:* December 2018. F Braun and C Condon updated the main text and Figs. 1, 4 and 7. Additional articles were added for further reading.

This article is an update of C. Condon, RNA Processing, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 395–408.

Fig. 1 Venn diagram of ribonucleases identified in bacteria. Exoribonucleases (Exos) are above the horizontal dividing line, mostly in *blue type* and represented by a “Pacman” symbol. Endoribonucleases (Endos) are below the dividing line, mostly in *black type* and represented by a scissors symbol. Enzymes unique to *E. coli* are in the *blue square* on the left, those unique to *B. subtilis* are in the *pink square* to the right, and those in common are in the *gray square* in the center. Essential enzymes are in *bold red type*. Shared enzymes that are essential to *B. subtilis*, but not *E. coli* are in *black type* on the *E. coli* side of the Venn diagram, and in *red type* on the *B. subtilis* side. RNase J1 and J2 are in *gray type* as endonucleases as the relevance of this activity in vivo is under question. Only two bacterial enzymes have so far been identified that are not present in either *E. coli* or *B. subtilis*, Barnase, found in some Gram-positive species, and Cas6, part of the CRISPR defense mechanism.

either hydrolytic, consuming a molecule of water upon the breaking of each phosphodiester bond, or phosphorolytic, using inorganic phosphate instead. Most RNases are hydrolases. Not surprisingly, bacterial RNases have been studied most extensively in *E. coli*. In recent years, however, significant progress has been made in *B. subtilis*, where 22 RNases have now been identified (vs. 26 in *E. coli*) and it is clear that most of the enzymes are different from those of *E. coli* (only 9 are in common). While *E. coli* appears to only possess 3' exoribonucleases, for example, exonucleases of either orientation (5' or 3') can be found in *B. subtilis* (as in eukaryotes). A Venn diagram showing the full set of currently known RNases of *E. coli* and *B. subtilis* is shown in Fig. 1. Many of these enzymes have specialized functions in RNA processing, which we will describe as we go along. The three-dimensional structures of many of these enzymes are known, permitting dissection of their activity mechanisms at the molecular level (indicated by an asterisk in Fig. 1).

Messenger RNA Processing

Ribonuclease processing of mRNAs leading to an increase in stability over the primary transcript has been described in a number of cases in both Gram-negative and Gram-positive bacteria. In many of the examples described in the literature, an endonucleolytic cleavage event occurs in the intergenic region between two open-reading frames encoded by the same RNA, maintaining the translational integrity of each fragment. In many cases, however, the upstream and downstream products of the cleavage reaction have different chemical and functional half-lives. Such mechanisms are typically exploited to produce different stoichiometric amounts of different products of the same operon. A regulator of an operon, for example, is often required in much lower quantities than the enzymes or structural components of the cognate pathway and thus the RNA fragment encoding a regulatory protein is typically destabilized by this kind of processing event, while the remaining fragment remains relatively resistant to RNases.

Messenger RNA Processing in *E. coli*

RNase E is the primary enzyme involved in intergenic RNA processing in *E. coli*. This is without doubt the key endoribonuclease of *E. coli*, and plays a role in mRNA processing and decay, and in stable RNA maturation. It is a large (1061 amino acids), essential protein that has an N-terminal catalytic domain and an intrinsically disordered C-terminal domain permitting both association with the inner membrane and interactions with other proteins, such as the RNA helicase RhlB, the 3' exoribonuclease

polynucleotide phosphorylase (PNPase), and the glycolytic enzyme enolase. This complex is known as the degradosome and similar RNase E-based degradosomes have been found in many organisms, with some interesting variations in the associated proteins. Although the importance of the degradosome in *E. coli* RNA decay is generally accepted, its role in RNA processing is less clear. Only the catalytic domain is necessary for the maturation of 5S rRNA and the RNase P RNA subunit, for example. The structure of the catalytic domain of RNase E has been solved in complex with RNA ([pdb 2C0B](#)). *E. coli* also possesses a nonessential paralog of the catalytic domain of RNase E, known as RNase G. Both enzymes have overlapping (although nonidentical) cleavage site specificities, that is to say, AU-rich single stranded regions.

Other enzymes, such as RNase III and RNase P, have been implicated in intergenic cleavages of a small number of specific mRNAs in *E. coli* and *Salmonella*. These enzymes play a more important role in rRNA and tRNA maturation and will be described in more detail later.

The *rpsU dnaG rpoD* operon

One of the first described examples of intergenic processing of mRNA in *E. coli* was the *rpsU dnaG rpoD* operon, encoding ribosomal protein S21, the DNA primase DnaG and the sigma-70 subunit of RNA polymerase, respectively ([Fig. 2A](#)). Primary transcripts of this operon are transcribed from tandem promoters and extend to either a weak transcription terminator located between *rpsU* and *dnaG* or a strong terminator at the 3' end of the operon. The long primary transcripts are cleaved between the *dnaG* and *rpoD* open reading frames by RNase E, leading to rapid degradation of the DnaG-encoding upstream portion and a stable downstream fragment encoding sigma-70. The terminator hairpin between *rpsU* and *dnaG* presumably protects the S21-encoding RNA from attack by 3' exoribonucleases degrading the *dnaG* RNA fragment. The particular processing and degradation pattern of this operon leads to the production of an estimated 50,000 molecules of S21, 50 molecules of DNA primase and 3000 copies of sigma-70 per cell.

The *pap* operon

The *pap* locus of uropathogenic *E. coli* strains encodes 11 proteins involved in pilin formation. Transcription of the rightward operon begins at the *papB* promoter and is attenuated at a terminator hairpin downstream of the second cistron *papA* ([Fig. 2B](#)). The *papBA* primary transcript is processed between the two open reading frames by RNase E, and the upstream fragment, encoding the regulator of the operon PapB, is rapidly degraded, while the downstream portion, encoding the major pilin protein PapA, is stable. The primary transcript has a half-life of 2.5 min while that of the PapA encoding fragment is 27 min, accounting in large part for the relative proportions of the regulatory and structural proteins of this operon.

Many other examples of intergenic processing have been found in *E. coli*, too numerous to describe here. The principle is always the same; endonucleolytic cleavage followed by selective degradation of the upstream fragment by 3' exonucleases, while the downstream fragment remains relatively stable.

Bacteriophage mRNA Processing

Bacteriophage mRNAs tend to be highly processed. In some cases, the processing event does not lead to an increase in mRNA stability but rather to an increase in translation. The *N* gene of phage lambda and the *0.3* gene of phage T7 are two such examples.

The lambda *N* gene

The *N* gene of lambda is the first gene transcribed from the P_L promoter of the leftward operon. Transcription of the *nutL* sequence between the P_L promoter and the *N* gene leads to the assembly of an antitermination complex on RNA polymerase, that includes the *nut* RNA itself, the *N* protein and at least four host factors NusA, NusB, NusG and ribosomal protein S10 ([Fig. 3A](#)). This antitermination complex is critical for lambda development, as it allows RNA polymerase to read through multiple transcription terminators in this operon. The proximity of the *N* protein in the antitermination complex to its own Shine Dalgarno (SD) also causes steric inhibition of ribosome binding and hence auto-repression at the translational level. This translational auto-repression can be relieved (about 200-fold) by cleavage of a hairpin structure between *nutL* and the ribosome binding site by the double-strand nuclease RNase III, freeing up the SD element for ribosome binding. Lambda development is therefore highly sensitive to the RNase III activity of its host. As we will see below RNase III is occupied primarily in rRNA maturation in *E. coli*. Thus, changes in growth conditions, which affect rRNA synthesis, would be predicted to temporarily alter the amount of free RNase III in the cell and have a knock-on effect on lambda growth.

The phage T7 *0.3* gene

Bacteriophage T7 early mRNAs are quite stable, with half-lives in the 10–20 min range. A 7 kb precursor transcript, made by the host RNA polymerase soon after infection, is processed in five places by RNase III ([Fig. 3B](#)). In most cases, RNase III processing occurs on the distal side of hairpin structures, creating recessed 3' ends that are resistant to 3' exoribonuclease action, likely accounting for the high degree of early transcript stability. The *0.3* gene is the first gene of the early T7 operon and it plays a role in relieving host DNA restriction. Like the lambda *N* gene, the *0.3* gene transcript possesses a stem-loop structure in its 5' untranslated region. This hairpin is also cleaved on its distal side by RNase III. The stability of the downstream *0.3* portion of the transcript is unaffected by processing, however. Like lambda *N*, processing rather appears to influence the accessibility of the SD sequence to ribosome binding.

Fig. 2 Processing of mRNA in *E. coli*. (A) Organization of the *rpsU dnaG rpoD* operon and processing of its primary transcripts. Operon promoters are indicated as P_1 and P_2 . Open reading frames and their orientation are indicated by light blue arrows. Rho-independent transcription terminators (ter) are also shown. Transcripts are indicated by wavy lines and amounts detected in vivo are roughly proportional to the thickness of the lines. The site of RNase E cleavage in the intergenic region between *dnaG* and *rpoD* is represented by a blue scissors. (B) Organization of the *pap* locus of uropathogenic *E. coli* and processing of its primary transcripts. Promoters are indicated as P_1 and P_2 . Other symbols and conventions are as in (A). The 3' end of the long rightward *pap* transcript is unknown and indicated by a question mark.

Retroregulation of the lambda *int* gene

The lambda *int* gene, encoding the integrase protein, provides an example where processing leads to a decrease rather than an increase in mRNA stability. One can justify considering this a processing pathway rather than a simple RNA decay mechanism on the grounds that targeted degradation of the *int* mRNA is part of a regulatory switch that determines whether the phage will enter the lysogenic or lytic development cycle. The *int* gene of lambda is transcribed from either the P_1 or P_L promoter, depending on the stage of the phage life-cycle, but only the P_1 transcript is translated. The P_1 transcript traverses the *int* gene and ends at a Rho-independent terminator immediately downstream. The P_L transcript, as we saw earlier, is synthesized by terminator-resistant RNA polymerase, and extends further downstream. The longer read-through transcript can fold into a hairpin structure called *sib*, which is a site for endonucleolytic processing by RNase III (Fig. 3C). Cleavage at this site provides access to the mRNA by the 3' exoribonuclease PNPase (pdb 1E3P) and the *int* transcript is rapidly degraded. In this mode, the phage does not synthesize the integrase protein and remains in the lytic cycle. This phenomenon has been called retroregulation because the regulatory elements are located downstream of the target gene.

Messenger RNA Processing in *B. subtilis*

Examples of mRNA processing have also been seen in *B. subtilis*. Interestingly, many Gram-positive bacteria do not possess RNase E or RNase G homologs, with the *Clostridia* and the *Actinobacteria* being notable exceptions. Although there has been evidence for some time of an RNase E-like activity in *B. subtilis*, the identity of this enzyme remained elusive until recently. Although RNases J1 and J2 were originally proposed to fulfill this role, there is now a general consensus that a different enzyme, RNase Y, is the functional analog of RNase E in *B. subtilis*, despite a complete lack of homology between the two enzymes. RNase Y has similar cleavage specificity to RNase E and is found associated with the membrane through its N-terminal trans-membrane domain like its protobacterial analog.

Fig. 3 Processing of phage mRNA. (A) Transcriptional and translational control of the lambda *N* gene. The top panel shows the assembly of the antitermination complex on the leftward operon of lambda, transcribed from promoter P_L . A similar complex is formed during transcription of the rightward operon from promoter P_R . The *N* open reading frame is indicated by a leftward oriented arrow. The positions of *nutL*, RNase III hairpin (hp) and Shine-Dalgarno (SD) elements are indicated. Transcription of *nutL* by RNA polymerase (RNA Pol) leads to the formation of an antitermination complex, containing the *nutL* RNA itself, *N* protein, and host factors NusA, NusB, NusG and NusE (=ribosomal protein S10), represented by the letters A, B, G and E, respectively. The 5' end of the *N* transcript (represented by a curved black line) remains attached to RNA polymerase through the interaction with *nutL*. In this conformation, ribosomes do not have access to the SD element of the *N* coding sequence. The lower panel shows cleavage of the hairpin (hp) by RNase III, freeing up the SD element for ribosome binding and translation of *N*. (B) Organization of the phage T7 early operon and processing of its primary transcript. The operon's three promoters (P) are indicated by the triple headed arrow. Open reading frames and their orientation are indicated by brown arrows. The operon's Rho-independent transcription terminator (ter) is also shown. Transcripts are indicated by wavy lines and sites of RNase III cleavage in five intergenic regions are indicated with blue arrows. (C) Organization of the phage lambda leftward operon and retroregulation of *int* gene expression. For description, see text. Promoters are indicated as P_L and P_I . Open reading frames and their orientation are indicated by light blue arrows. The transcription terminator (ter) and site of RNase III cleavage (sib) are indicated. PNPase is represented by a red "Pacman" symbol.

RNase Y has been proposed to be a scaffold for a degradosome-like network (DLN) in *B. subtilis* involving PNPase, an RNA helicase, CshA, and glycolytic enzymes. It has also been shown to interact with three proteins, YlbF, YmcA and YaaT, to form a separate complex, known as the Y-complex. Although RNase Y has mostly been shown to be involved in mRNA turnover, a number of RNase Y-dependent cleavages have been discovered that can be considered as processing events. Recent data suggest that the Y-complex might be specifically involved in RNase Y processing events allowing differential abundance of mRNA fragments.

In addition to RNase Y, *B. subtilis* has another major RNA enzyme involved in RNA processing and decay, the 5'-exoribonuclease RNase J1. While neither RNase J1 nor RNase Y are essential on their own, a double mutant lacking RNase Y and RNase J1 is inviable, as is a double mutant lacking RNase J1 and the 3'-exoribonuclease PNPase. RNase J1 forms a complex with its paralog RNase J2, with RNase J1 providing most of the 5'-exonucleolytic activity. Although both enzymes have endonucleolytic activity at high concentrations in vitro, the in vivo relevance of this additional activity is not clear. *B. subtilis* RNase J1 is a member of the β -CASP family of metallo- β -lactamases and its structure has been solved (pdb 3ZQ4). Genome analysis has revealed that most bacterial phyla contain at least two of three major ribonucleases: RNases E/G, J, or Y.

The *thrS* mRNA

The threonyl-tRNA synthetase gene of *B. subtilis* *thrS* is one of about 20 so-called T-box genes in this organism, regulated by a tRNA-dependent antitermination mechanism. Genes regulated by this mechanism are involved in amino acid metabolism and are sensitive to the ratio of uncharged to charged levels of the cognate tRNA. Hence, expression of the *B. subtilis* *thrS* gene is induced in response to threonine starvation. Binding of uncharged tRNA^{Thr} to the *thrS* leader sequence stabilizes an antiterminator structure in the mRNA at the expense of a mutually exclusive transcription terminator upstream of the *thrS* coding sequence. Under threonine starvation conditions, the major 5' end found in vivo corresponds to a processing event that occurs nine nucleotides (nts) upstream of the leader terminator hairpin (Fig. 4A). The cleaved transcript is about fivefold more stable than the primary transcript, presumably due to the presence of a hairpin structure protecting each extremity from further degradation by exonucleases. At least five other T-box mRNAs are processed in a similar manner just upstream of the leader terminator and thus this appears to be a general mechanism to amplify the antitermination effect for this family of genes in *B. subtilis*. Although cleavage at this site was originally attributed to the endonucleolytic activity of RNase J1/J2 based on in vitro studies, it was subsequently shown that RNase Y is a more likely candidate for this cleavage in vivo. Indeed, the leader regions of at least five of the six T-box mRNAs known to be processed upstream of their terminators accumulate in strains depleted of RNase Y, but not in strains depleted of RNase J1.

The *hbs* gene

Evidence for mRNA processing by RNase J1, exploiting its 5' exoribonuclease activity, has also been seen in *B. subtilis*. The *hbs* gene, is transcribed from two promoters, about 210 and 180 nts upstream of the open reading frame encoding the histone-like protein HU. A third major transcript is also observed in vivo, whose 5' end maps about 20 nts upstream of the *hbs* start codon. Although originally thought to represent transcription from yet another promoter, the 5' end of this stable transcript is in fact generated by 5'-exoribonuclease digestion of the *hbs* mRNA by the RNase J1/J2 complex until it bumps up against ribosomes initiating translation at its very strong Shine-Dalgarno (SD) sequence. Increasing the strength of the *hbs* SD increases the level of this mRNA species in the cell, while weakening only slightly it causes this transcript to disappear completely (Fig. 4B). The 5' ends of the two primary *hbs* transcripts are highly protected by secondary structure. RNase Y cleaves in the 5'-UTR sequence, allowing RNase J1/J2 access to the mRNA just upstream of the ribosome. Such a pathway potentially provides a built-in destruction mechanism for the *hbs* RNAs once it has surpassed its usefulness for translation, as access to the coding sequence is no longer protected by ribosomes from 5'-exonucleolytic attack. A similar example of processing and RNA protection by ribosomes has been identified for the *cryIIIA* mRNA, encoding the insecticidal crystal toxin of *B. thuringiensis*, expressed in *B. subtilis*. In this case a strong SD-like sequence with no associated start codon, called the stab-SD, binds a 30S ribosomal subunit and blocks RNase J1/J2 progression, stabilizing the mRNA for many kilobases downstream.

Intergenic mRNA processing

Several cases of intergenic processing have been described in *B. subtilis*, similar to those described for the *rpsU dnaG rpoD* and *papBA* operons of *E. coli* above. The best known examples are those of the *gap* operon, encoding six genes involved in the interconversion of triose phosphates of the glycolytic pathway (Fig. 4C), and the *dnaK* heat shock operon (Fig. 4D). In both of these cases, processing occurs between the first and second ORFs of the operon. The RNA fragment containing the first ORF, encoding the regulator of the operon is quickly degraded, while the downstream fragment is relatively stable. The differential stability of the upstream and downstream cleavage products can account for the differences in stoichiometry between the regulator and other proteins of the operon. RNase Y has been shown to be responsible for the cleavage in the *gapA* operon mRNA. This processing event was recently shown to require the Y-complex. Interestingly, the *cggR (gapR)-gapA* operon of *S. aureus* is similarly matured by RNase Y and requires YlbF, one of the Y-complex proteins, suggesting that the function of the Y-complex is conserved among the Firmicutes.

Stable RNA Processing

Ribosomal RNA Processing

In *E. coli* and *B. subtilis*, ribosomal RNAs are transcribed from *rrn* operons containing the genes for 16S, 23S and 5S rRNA, in that order, sometimes interspersed with tRNAs (Fig. 5A). Although this is the most commonly encountered scenario throughout the

Fig. 4 Processing of mRNA in *B. subtilis*. (A) Antitermination and processing of the *thrS* transcript. The left panel shows binding of tRNA^{Thr} (red cloverleaf structure) to the *thrS* leader mRNA, stabilizing the antiterminator hairpin. The position of suspected RNase Y cleavage is indicated by a blue scissors. The right panel shows the transcriptional organization of the *thrS* gene, with promoter (P) and terminators (ter). Transcripts are indicated by wavy lines, with the thickness of the line roughly proportional transcript abundance in vivo. (B) Organization of the *B. subtilis hbs* gene and processing of its transcript. The 5' exoribonuclease activity of the RNase J1/J2 complex is represented by a "Pacman" symbol. The RNase Y cleavage is indicated by a scissors symbol. Ribosomal subunits are represented by purple ovals. Nucleotide coordinates are given above the *hbs* transcript, indicated by a wavy line. (C) Organization of the *gap* operon and processing of its primary transcripts. Symbols and conventions are the same as in previous figures. RNase J1 is the prime candidate for cleavage at the site indicated by the scissors symbol. (D) Organization of the *dnaK* heat-shock operon and processing of its primary transcripts. Symbols and conventions are the same as in previous figures. RNase J1 is also the prime candidate for cleavage at the site indicated by the scissors symbol.

Fig. 5 Processing of rRNA in *E. coli* and *B. subtilis*. (A) General organization of rRNA operons. Transcription begins at tandem promoters (P_1 and P_2) and ends at the transcription terminator (ter). Transfer RNA genes [tRNAs] sometimes occur in the spacer regions between the 16S and 23S rRNA genes or downstream of the 5S gene. (B) Processing of 16S rRNA in *E. coli* (left) and *B. subtilis* (right). The mature 16S sequence is in light blue, precursor sequences in black. The number of extra nts remaining following processing at each site is indicated below the enzyme in question. Unknown enzymes are indicated in red type. Endonucleolytic cleavages are represented by black arrows perpendicular to the transcript; exonucleolytic digestion is represented by black arrows parallel to the transcript. Although the different cleavage steps are numbered, the order of cleavages is not obligatory for 16S rRNA maturation in either organism. Adapted from Britton et al. (2007). *Molecular Microbiology* **63**,127–138. (C) Processing of 23S rRNA in *E. coli* (left) and *B. subtilis* (right). The mature 23S sequence is in green, precursor sequences in black. Mini-III processing of *B. subtilis* 23S rRNA requires r-protein L3. Symbols and conventions are as in (A). In *E. coli*, RNase III cleavage is an obligatory first step for generation of mature 5' and 3' ends. The order of steps 2 and 3 is not known. In *B. subtilis*, accurate maturation can occur in the absence of RNase III. (D) Processing of 5S rRNA in *E. coli* (left) and *B. subtilis* (right). The mature 5S sequence is in mauve, precursor sequences in black. RNase M5 processing of *B. subtilis* 23S rRNA requires r-protein L18. Symbols and conventions are as in (A). As for 16S rRNA, prior cleavage by RNase III is not obligatory in either organism.

bacterial kingdom, there are scattered cases where the 16S and 23S genes are not cotranscribed. The *rrn* operons of *E. coli* and *B. subtilis* are transcribed as long 30S precursor RNAs from tandem promoters upstream of the operon. The 5' and 3' flanking sequences of both 16S and 23S rRNA can base pair to form long "processing stalks" which are substrates for RNase III. RNase III is the founder member of a large family of double-stranded RNases including Dicer, well known for its role in posttranscriptional gene silencing in eukaryotes. RNase III consists of an N-terminal catalytic domain and a C-terminal double-stranded RNA binding domain (dsRBD) and forms dimers (pdb 1RC7). It generally cleaves on both strands of long double-stranded helices to produce RNAs with a recessed 5' end and a 2-nt 3'-overhang. Particular sequence and structure contexts can cause it to cleave on just one of the two strands, however. In *E. coli*, RNase III cleavage of the 30S rRNA precursor is known to occur as it is being transcribed and leads to separation of the 16S, 23S and 5S rRNA species. Processing by RNase III is not absolutely necessary for the production of functional rRNAs in either of these two organisms, however. The RNase III-generated processing intermediates are whittled down to their mature sizes by other enzymes, in many cases subsequent to subunit assembly or even translation initiation. With one notable exception (see below), the enzymes responsible for the late steps of rRNA maturation in *B. subtilis* have proven to be different to those in *E. coli*. In fact, in most cases, the enzymes involved are unique to each species.

16S rRNA maturation

The mature 5' side of *E. coli* 16S rRNA is generated by the cooperative action of RNase E and RNase G (Fig. 5B). RNase E first cleaves 66 nts from the mature 5' end and this facilitates the final endonucleolytic cleavage by RNase G, presumably by permitting some structural rearrangement of the RNA. These reactions occur after ribosome assembly.

In *B. subtilis*, 16S rRNA 5' maturation is catalyzed by the 5'-exoribonuclease activity of RNase J1, presumably in complex with RNase J2, since this is the primary form of both enzymes found *in vivo*. Some feature close to the 5' end of 16S rRNA in the assembled ribosome, for example, a bound ribosomal protein, is required to tell RNase J1 where to stop. A processing intermediate, generated by an unknown RNase, accumulates 38 nts from the mature 5' end in *B. subtilis* cells lacking RNase J1.

Two different pathways have been proposed for the maturation of the 3' end of 16S rRNA in *E. coli*. One involves a new enzyme called YbeY (pdb 1XM5). Although a mutation in the *ybeY* gene was shown to affect processing of all three rRNAs, it was proposed that YbeY specifically catalyzes the endonucleolytic processing of the 3' end of 16S rRNA. Another group has more recently proposed that 3'-maturation can also be catalyzed by a number of redundant 3'-exoribonucleases including PNPase, RNase PH, RNase R and RNase II. One of these enzymes, RNase R, has also been shown to perform exonucleolytic trimming of 16S precursors in the psychrophilic γ -Proteobacterium *Pseudomonas syringae*. Recently, it was shown that the 3' processing pathway of 16S rRNA in *B. subtilis* involves the YqfG enzyme, an ortholog of *E. coli* YbeY. Indeed, the *B. subtilis* *yqfG* gene can complement the *E. coli* *ybeY* deletion mutant for 16S rRNA processing. In contrast to *E. coli* YbeY, YqfG is essential in *B. subtilis*, but the lethality of the *yqfG* gene knockout can be suppressed by also deleting the gene encoding RNase R (*rnr*). This suggests that, unlike the proteobacterial RNase R, which can act in an alternative processing pathway for 16S rRNA 3'-maturation, RNase R in *B. subtilis* acts mainly in a quality control pathway to rapidly degrade 16S rRNA species that YqfG has failed to process. In the absence of RNase R, 16S rRNA species with 3'-extensions, which would be expected to be highly inefficient in translation, accumulate to sufficient levels to allow enough translation for cell viability.

23S rRNA maturation

Although accurate processing of *E. coli* 16S rRNA still occurs in the absence of RNase III, maturation of 23S rRNA fails completely. Thus, RNase III processing is an obligatory first step for 23S rRNA maturation in this organism. The 23S precursor RNA can still be assembled into functional ribosomes, however. RNase III cleavage of the 23S precursor produces an intermediate species with three to seven extra nucleotides on the 5' end and seven to nine extra nucleotides on the 3' end (Fig. 5C). The enzyme responsible for the subsequent generation of the mature 5' end remains unknown, while the 3' end is matured by the distributive 3'-exoribonuclease RNase T. RNase T (pdb 2F96) is an important enzyme in *E. coli* that can degrade to within one or two nucleotides of double-stranded stems. It is a member of the DEDD family of exoribonucleases that includes oligoribonuclease, which degrades small oligonucleotides in the 2–5 nt range, and RNase D, which is involved in tRNA maturation (see below). The final maturation steps of both the 5' and 3' end of *E. coli* 23S rRNA are most efficient under conditions of protein synthesis, suggesting that some structural rearrangement occurs at the onset of translation that allows better access to the two extremities.

Maturation of 23S rRNA in *B. subtilis* follows a different pathway than *E. coli*. In this case, the base-paired 5' and 3' ends of 23S rRNA are matured by an enzyme homologous to the catalytic domain of RNase III, and lacking the dsRBD, called Mini-RNase III (pdb 4OUN). Endonucleolytic cleavage by Mini-III on both sides of the processing stalk to directly yield 5'- and 3'-mature 23S rRNA requires prior binding of the large subunit RNA by the ribosomal protein L3. This provides a potential quality control check for correct ribosome assembly before proceeding with the final maturation step. Interestingly, this L3 quality control step is also used in the maturation of the large subunit RNA in *S. cerevisiae*, but with a different processing enzyme. In *B. subtilis*, prior cleavage of the large 23S processing stalk by RNase III is not necessary for Mini-III action, and an alternative back-up pathway exists in Mini-III deletion mutants (Δ *rrnC*) that results in slightly different 5' and 3' ends. This pathway is catalyzed by exoribonucleases: RNase J1 at the 5' end and RNases PH and YhaM at the 3' end, but its physiological relevance is unknown. It may be the vestige of an older pathway that can also be found in some proteobacteria such as *Sinorhizobium meliloti*.

Some variations on the pathways of 23S rRNA processing can be seen in other organisms. In some species, including *Salmonella*, the 23S rRNA contains short intervening sequences that require removal by RNase III processing. In these cases, the "23S" rRNA is assembled into 50S subunits as fragments. In *Deinococcus radiodurans*, maturation of the 3' end of 23S rRNA is catalyzed principally by RNase PH and RNase II.

5S rRNA maturation

RNase III processing of 23S rRNA releases the 5S rRNA precursor in both *E. coli* and *B. subtilis* and defines the 5' end of the naturally occurring precursor species. The 3' end is quite variable, however, and depends on the distance to the terminator hairpin or downstream tRNA for each of the individual *rnn* operons (there are 7 of these in *E. coli* and 10 in *B. subtilis*). Once again, these two organisms have found very different strategies for the final maturation steps of an rRNA. In *E. coli*, RNase E cleaves in a single-stranded region on either side of the 5S rRNA, producing an intermediate species with three extra nucleotides at each end (Fig. 5D). The 3' exonuclease RNase T catalyzes the final maturation of the 3' end, while the enzyme that removes the 3 nts from the 5' end is still unidentified. In *P. syringae*, the 3' maturation reaction is carried out by RNase R at cold temperatures.

B. subtilis, on the other hand, uses the double-stranded maturase RNase M5, cleaving once on each strand and producing the mature 5S rRNA in a single endonucleolytic step. RNase M5 is a small protein (20.5 kDa) that belongs to the Toprim domain family of enzymes, including the topoisomerases and the primase DnaG. It is essentially confined to the low G + C Gram-positive bacteria. Cleavage requires the binding of ribosomal protein L18 to 5S rRNA, presumably to fold it correctly for processing. Thus, like 23S rRNA, final processing of 5S rRNA is subjected to a quality control step. Strains lacking RNase M5 can no longer mature 5S rRNA, but yet are viable despite the presence of long (up to 165 nts) 5S rRNA precursors in their translating ribosomes.

Transfer RNA Processing

Transfer RNA genes are found in many different contexts in bacteria, as single transcription units, cotranscribed with other tRNAs, or cotranscribed with other components of the translational apparatus, such as ribosomal RNAs or elongation factors. In *E. coli*, all tRNAs have the so-called CCA motif encoded by their genes. This is the single-stranded motif found at the 3' end of all tRNAs to which the cognate amino acid is attached. In *B. subtilis*, about one third of tRNA genes lack the CCA motif and in these cases the CCA is added posttranscriptionally by an enzyme called nucleotidyl transferase. The proportion of tRNA genes with a CCA motif in any particular organism is extremely variable throughout the bacterial kingdom, ranging from all to none and everything in between. As we shall see this plays an important role in determining which of two possible tRNA maturation pathways is used for the 3' processing of a particular tRNA.

All tRNAs, even those that occur as single transcription units, are synthesized as primary transcripts bearing extraneous sequences at both their 5' and 3' ends. The 5' extensions are universally removed by the endoribonuclease RNase P (Fig. 6). RNase P is a fascinating enzyme consisting of a catalytic RNA subunit and a protein subunit, both of which are essential. The 13 kDa protein subunit has been proposed to play multiple roles, the most important of which appears to be to increase the affinity of the 350–400 nt RNA subunit for the precursor tRNA, by changing its conformation near the tRNA binding site. The crystal structure of RNase P holoenzyme bound to tRNA has been solved (pdb 3Q1Q). Two different protein-only forms of RNase P have also been identified, one in some bacteria, notably the *Aquificaceae* (HARP), and the archaea, and one found only in eukaryotes (PRORP), but the ribozyme form is by far the most dominant form found in nature.

Fig. 6 Processing pathways of tRNAs in *E. coli* and *B. subtilis*. (A) Exonucleolytic pathway. The mature tRNA is represented by a red cloverleaf structure, precursor sequences in black. Endonucleolytic cleavages are represented by black arrows perpendicular to the transcript; exonucleolytic digestion is represented by black arrows parallel to the transcript. The key 3' exonucleases are in bold type. In *E. coli*, extremities accessible to the 3' exonucleases are often generated by prior cleavage by RNase E. An RNase T-like enzyme remains to be identified in *B. subtilis*. (B) Endonucleolytic pathway. The “mature” tRNA is represented by a red cloverleaf structure, although this requires further addition of the CCA motif by nucleotidyl transferase, with the discriminator base (N) and the downstream uracil (U) residue indicated. Symbols and conventions are as in (A). Adapted from Redko et al. (2007). *Nature Reviews Microbiology* 5, 278–286.

Maturation of the 3' end of tRNAs can occur via a primarily exonucleolytic or endonucleolytic pathway, depending mainly on the presence or absence of a CCA motif in the precursor species. In *B. subtilis*, an enzyme called RNase Z endonucleolytically cleaves those tRNA precursors lacking a CCA motif. RNase Z is a member of the Zn-dependent metallo- β -lactamase family of enzymes, like RNase J. The structure of RNase Z has been solved in complex with tRNA (pdb 2FK6). RNase Z generally cleaves tRNA precursors just downstream of the discriminator nucleotide, the unpaired nucleotide (labeled N in Fig. 6) at the 3' end of the acceptor stem. Most CCA-less *B. subtilis* tRNAs have a naturally occurring uracil (U)-residue immediately downstream of the cleavage site and RNase Z activity is stimulated >200-fold by the presence of this residue, explaining why this class of tRNAs is a preferred substrate for RNase Z. In fact, the U-residue also determines the site of initial cleavage. For the few CCA-less tRNA precursors where the U-residue is one or two nucleotides further downstream of the discriminator base, endonucleolytic cleavage occurs just 5' to the U-residue and then the enzyme chews back to the discriminator base in 3'-exonucleolytic mode. Like many of the ribonucleases of the β -lactamase family, RNase Z has both *endo*- and exonuclease activity.

The 3'-exonucleolytic tRNA maturation pathway was first discovered in *E. coli*. Here, any of at least four redundant 3' exonucleases, RNase PH, RNase T, RNase D and RNase II can perform the task, with the first two distributive enzymes being the most important. Should any of these RNases degrade into the CCA motif present in *E. coli* tRNA precursors, the damage can be repaired by nucleotidyl transferase. RNase PH (pdb 1OYP) is primarily involved in maturation of small stable RNAs and is a member of the PDX family of phosphorolytic 3'-exonucleases that includes PNPase. Homologs of RNase PH form the hexameric core of the eukaryotic exosome that plays an important role in both mRNA degradation and stable RNA maturation. RNase D (pdb 1YT3) is a distributive enzyme, also dedicated to small stable RNA 3'-maturation in *E. coli* and a member of the same family of RNases as RNase T. A homolog of RNase D is also associated with the yeast nuclear exosome. Finally, RNase II (pdb 2IX1) is processive 3'-exoribonuclease that plays a more important role in mRNA degradation. In the absence of these four redundant 3' exonucleases, sufficient tRNA 3' maturation can be performed by RNase Z (also known as RNase BN) in 3'-exonuclease mode to maintain viability in *E. coli*. RNase Z progression is halted by the C residues of the CCA motif.

Of the four enzymes implicated in the *E. coli* 3'-exonucleolytic tRNA maturation pathway, only RNase PH is found in *B. subtilis*. *B. subtilis* strains lacking RNase PH accumulate precursors of those tRNAs with an encoded CCA motif. These precursors are 1–4 nts longer than the mature tRNA species, indicating that RNase PH plays a key role in the removal of the last few precursor nucleotides from the 3' end. RNase PH null mutants still produce large quantities of accurately matured CCA-containing tRNAs, indicating that other enzymes can perform the same function. Indeed, *B. subtilis* strains lacking from one to four of its known 3'-exoribonucleases, RNase PH, PNPase, RNase R and YhaM accumulate progressively longer tRNA precursors, suggesting that, as in *E. coli*, multiple redundant RNases can perform the maturation reaction. PNPase is a processive phosphorolytic enzyme, related to RNase PH, whose principal role is mRNA degradation. RNase R is a processive hydrolytic 3'-exonuclease, with a much better ability to degrade through RNA secondary structures than either PNPase, or its cousin RNase II. It is known to play a major role in rRNA degradation and, more recently, in the decay of structured portions of mRNAs. The primary RNA substrates of YhaM are unknown and this enzyme is also thought to play an important role as a DNase in *B. subtilis*. In the absence of other 3'-exoribonucleases, YhaM can clearly provide some back-up, however, as we saw for 23S rRNA. At least one other enzyme, likely to have an RNase T-like function, remains to be identified in the 3'-exonucleolytic tRNA maturation pathway in *B. subtilis*, since a significant portion of all CCA-containing tRNAs are still correctly processed at their 3' ends in strains lacking these four enzymes.

Processing of Other Stable RNAs

A number of small stable RNAs with specific properties have been identified in *E. coli* and *B. subtilis*. These too are synthesized as precursors requiring maturation by RNases. Identification of the RNases involved underscores the idea that the maturation pathways of stable RNAs are generally very different in these two organisms.

4.5S/scRNA Maturation

The 4.5S RNA of *E. coli* and its equivalent in *B. subtilis*, called small cytoplasmic RNA (scRNA), are part of the signal recognition particle (SRP) whose function is to direct proteins bearing an N-terminal export sequence to the plasma membrane as they emerge from the ribosome. This RNA is synthesized as a precursor with 5' and 3' extensions in both *E. coli* and *B. subtilis*. In *E. coli*, 4.5S RNA is matured on the 5' side by RNase P and on the 3' side by exonucleolytic trimming. As for tRNA 3'-maturation, several of the 3'-exonucleases appear capable of contributing to this process, with RNase T playing the most important role (Fig. 7A).

B. subtilis has two possible pathways of scRNA maturation. The first step of both pathways is catalyzed by RNase III on the upstream side of a long double stranded region, to produce the mature 5' end directly. The 3' end is then generated either by a second, less efficient cleavage by RNase III on the 3' side of the stem, 4 nts downstream of the mature 3' end, or by endonucleolytic cleavage by RNase Y 12 nts downstream of the mature 3' end. In both cases, the final maturation step is catalyzed by 3' exonucleolytic trimming by redundant exonucleases, with RNase PH playing the predominant role. Although the cleavage by RNase Y is shown in a double-stranded region in Fig. 7A, it is thought that the maturation of the 5' side by RNase III permits rapid degradation of the fragment of RNA base-pairing with the RNase Y recognition site. Thus, these steps are likely to precede RNase Y cleavage.

Fig. 7 Processing of various small stable RNAs in *E. coli* and *B. subtilis*. (A) Processing of 4.5S/scRNA. The mature RNA is in *light blue*, precursor sequences in *black*. Endonucleolytic cleavages are represented by *black arrows* at an angle to the transcript; exonucleolytic digestion is represented by *black arrows* parallel to the transcript. The key 3' exonucleases are in *bold type*. (B) Processing of RNase P RNA. The mature RNA is in *mauve*, precursor sequences in *black*. Symbols and conventions are as in (A). Although most RNase P RNA is synthesized with a mature 5' end in *E. coli*, some precursor can be produced by read-through transcription from upstream genes (represented by a *dotted line*). The details of the processing pathway of these transcripts are unknown, but involves RNase E in *E. coli* and RNase Y in *B. subtilis*. (C) Processing of tmRNA. The mature RNA is in *red*, precursor sequences in *black*. Symbols and conventions are as in (A). (D) Processing of 6S RNA in *E. coli*. The mature RNA is in *green*, precursor sequences in *black*. Symbols and conventions are as in (A).

Maturation of the RNA subunit of RNase P

The RNA subunit of RNase P (also known as P-RNA or M1 RNA) is transcribed from the *mpB* gene as a precursor molecule. The main promoter of the *mpB* gene in *E. coli* produces a P-RNA that does not require further maturation at the 5' end. Longer RNAs resulting from read-through transcription from upstream genes accumulate in RNase E mutants, however, and there is some debate about whether these RNAs can produce functional P-RNA. Maturation of the 3' side of *E. coli* P-RNA requires cleavage by RNase E a few nts downstream, followed by exonucleolytic trimming. RNase T plays the most important role among the 3'-exonucleases of overlapping function (Fig. 7B).

B. subtilis P-RNA maturation, on the other hand, has been proposed to be autocatalytic. Indeed, accurate maturation of the 5' end of *B. subtilis* P-RNA can be efficiently catalyzed in vitro by the RNase P holoenzyme. It has also been proposed that RNase P processes its own 3', in this case producing a P-RNA 4 nts shorter than the mature species identified in vivo. While autocatalytic maturation of the 3' end is still possible, about 80% of RNase P RNA is in its precursor form in cells lacking RNase Y, strongly suggesting this is the major 3' processing enzyme in vivo.

Maturation of tmRNA

The transfer-messenger RNA (tmRNA or 10Sa RNA) plays an important role in the rescue and recycling of ribosomes stalled on truncated mRNAs. Its tRNA-like structure can be aminoacylated and inserted into the ribosome A-site. A conformational change then occurs on the ribosome that causes it to switch templates from the truncated mRNA to the tmRNA. The tmRNA encodes a small peptide tag that is added to the truncated protein, targeting it for proteolysis. Maturation of tmRNA has been characterized in *E. coli* (Fig. 7C). Not surprisingly, for a molecule whose 5' and 3' extremities come together to form a tRNA-like structure, maturation of tmRNA employs the same pathway as *E. coli* tRNAs. RNase P removes the 5' leader sequence, while the 3' exoribonucleases perform the 3' reaction. RNase R, which copurifies with tmRNA, has also been shown to play a role in 3' processing under conditions of cold growth. In *B. subtilis*, the tmRNA processing pathway is also very similar to that of its tRNAs. RNase P is responsible for processing at the 5' end, and since the tmRNA gene lacks the appropriate CCA motif for aminoacylation, RNase Z processes the 3' end. The CCA-motif is added subsequently to create a functional tmRNA, presumably by nucleotidyl transferase. Like the vast majority of tRNAs lacking an encoded CCA motif in *B. subtilis*, the tmRNA precursor also has a U-residue immediately downstream of the discriminator base to stimulate RNase Z cleavage.

Maturation of 6S RNA

The 6S RNA binds RNA polymerase and modulates sigma-70 holoenzyme activity in response to growth phase. It is thought to function as a mimic of the transcription bubble, thus inhibiting RNA polymerase activity. In *E. coli* 6S RNA is synthesized as a precursor molecule from two different promoters and has both 5' and 3' extensions. Transcription from the distal promoter P₂ is dependent on both sigma-70 and the stationary phase factor sigma-S, whereas the proximal promoter P₁ is sigma-70 dependent only. The long precursor is cleaved exclusively by RNase E to generate the mature 5' end of 6S RNA, while the short precursor can be processed by either RNase E or RNase G. Thus the biogenesis pathway of 6S is an interesting interplay between sigma factors and endoribonucleases. Maturation of the 3' side occurs via 3' exonucleolytic trimming, with RNases T and PH playing predominant roles.

The 6S RNA processing pathway has not yet been reported for *B. subtilis*.

Role of Precursors in Quality Control?

Why synthesize stable RNAs as precursors, rather than directly as mature species? Although it would be feasible for cells to synthesize RNAs directly with mature 5' ends, simply by adjusting the point of transcription initiation (and this indeed is the case for *E. coli* RNase P RNA), direct production of the mature 3' end is more difficult. This is because the transcription termination signals are transcribed into RNA, making at least one processing step, that is, removal of the terminator, almost unavoidable. It is also possible, however, to imagine that synthesis of stable RNAs as precursor molecules provides cells with a quality control option, by leaving "access-ramps" in place for exonucleases to degrade these RNAs should they prove to be nonfunctional. This idea is supported by the fact that the final steps of rRNA maturation generally only occur once subunit assembly is completed and, for some reactions, not until after the ribosome has initiated translation. Quality control mechanisms involving RNase R have been shown to exist in *E. coli* for rRNAs and tRNAs and these mechanisms rely on a re-synthesis of an exonuclease access-ramp by poly(A) polymerase. A similar phenomenon is seen with the role of RNase R in degrading unprocessed 16S rRNAs in *B. subtilis*. Moreover, in *B. subtilis*, RNase J1 can degrade 16S rRNA completely in 5'-exonuclease mode unless it is stopped by some feature of the assembled 30S subunit. This phenomenon could be, and likely is, exploited by the cell as a quality control mechanism for 30S subunit assembly, afforded by a 5'-extension. The intervention of ribosomal proteins L3 and L18 in 23S and 5S rRNA maturation is thought to play similar role in the quality control of these rRNAs.

Future Orientations

Although the majority of the processing reactions of stable RNAs have now been characterized in *E. coli* and *B. subtilis* there are still a few loose ends. The 6S processing pathway and the enzyme that gives access to RNase J1 for the maturation of the 5' end of 16S

rRNA remain to be identified in *B. subtilis*, as do the enzymes that catalyze the maturation of the 5' side of 23S and 5S rRNA in *E. coli*. The future of RNA processing probably lies outside of these two organisms, however. Many were taken by surprise by the extent of the differences between *E. coli* and *B. subtilis* maturation enzymes and pathways, despite their evolutionary distance (estimates vary between 1 and 3 billion years, greater than that of plants and animals). Clearly, other highly divergent model organisms, a representative of the archaea, for example, and perhaps a representatives of the cyanobacteria, require intense study before we can claim to have a global understanding of RNA processing throughout the prokaryotes.

Glossary

Ambisense RNA A viral single-stranded RNA genome or genome segment that contains protein coding sequences in the positive sense for some genes but in the negative sense for others. The positive sequences are not used directly as mRNA but are only expressed after sub-genomic RNA transcription.

Metagenomics Sequencing and analysis of DNA and RNA molecules present in the environment (for example, field-collected samples from viral hosts, vectors, or other materials). An important advantage is that this analysis does not depend upon isolation/culturing/purification of viruses/microorganisms.

Phloem In vascular plants, the conductive tissue responsible for transport of organic substances. Phloem consists of living cells and is the major conduit for systemic movement of viruses.

Plasmodesmata (sing. plasmodesma) Channels of cytoplasm existing between adjacent plant cells. Plasmodesmata penetrate the cell wall, allowing transfer of substances (including viruses or viral nucleic acids) between cells. Almost all plant cells, including those in the phloem, are interlinked in this way: A network sometimes referred to as the 'symplasm'.

Replicase A viral RNA-dependent RNA polymerase (RdRP) encoded by a virus, usually with additional enzyme activity (e.g., helicase, methyltransferase), and normally complexed with host factors (membranes, proteins). The replicase has the main function of generating new genomic RNA molecules but may also function as a transcriptase for synthesis of sub-genomic viral RNAs. The replicase should not be confused with RNA-directed RNA polymerase (RDR) enzymes that are encoded by a host cell, which synthesize short RNA molecules and are components of the RNA silencing mechanism.

RNA silencing A mechanism, which is highly conserved between plants and animals, that is important for antiviral defense, regulation of endogenous gene expression and control of transposons. RNA silencing comprises a number of different pathways that share related or overlapping components and that is guided by small (s)RNAs of 20–25 nucleotides in length. sRNAs bear high sequence homology to their target loci, which confers specificity on the silencing process. As a means of counter-defense, many plant viruses encode proteins that suppress RNA silencing.

Sense In the context of single-stranded RNA viruses, positive-sense genomes are those that can act directly as mRNA. However, given the constraints of the eukaryotic protein synthesis apparatus additional strategies may be employed to express genes that are not proximal to the 5' end of the genomic RNA molecule. Negative-sense RNA viruses express their proteins by synthesis of mRNAs that are complementary to the sequence of the encapsidated genomic RNA(s).

Sub-genomic RNA These RNA molecules are produced as a result of viral RdRP activity. They are shorter than full-length genomic RNAs but their nucleotide sequences are identical to a part of the viral genomic RNA. It is not always possible to ascribe a function to a sub-genomic RNA. However, many are known to function as mRNAs for the expression of viral proteins that cannot be synthesized using the genomic RNA as a translation template.

Systemic and local infection In a local infection the virus either remains in the directly inoculated cells or exhibits limited spread between cells in the inoculated organ(s) of the plant. Systemic infection occurs when the virus enters the vascular tissue and spreads (typically *via* the phloem) to tissues that were not directly inoculated with the virus.

Virion An individual, complete virus particle. Virions typically consists of a shell (capsid) of protein and/or lipid surrounding the viral genomic nucleic acid molecule(s).

Defining Statement

The article covers the genome organization, the replication and gene expression strategies of double-stranded and single-stranded (positive and negative sense) RNA viruses infecting higher plants. An overview of the mechanisms by which these viruses induce disease and suppress host resistance is also included.

Introduction

About 80% of the viruses known to infect flowering plants (angiosperms) have RNA genomes. Viruses with genomes consisting of single-stranded (ss) positive sense RNA constitute the single largest group of plant RNA viruses (c. 65%). The remainder have double-stranded (ds) or negative-sense ss RNA genomes (<5% and c. 10%, respectively) (Table 1). The discovery of new plant-

This article is a reprint of Mathew G. Lewsey, John P. Carr, RNA Viruses: Plant Pathogenic, *Reference Module in Life Sciences*, Elsevier, 2018.

^bIncludes fungus- as well as plant-infecting member species.

^cPlant-infecting members also able to infect insect vectors.

^dSub-family of Family *Betaflexiviridae*.

^eSub-family of Family *Secoviridae*.

infecting viruses, as with viruses in general, is accelerating due to the application of advanced nucleic acid sequencing techniques to environmental samples, an approach called ‘viral metagenomics’. Currently there are no known plant retroviruses. In addition to true RNA viruses, plants can also be infected by viroids, which are infectious agents consisting of small (240–380 nucleotide), circular ssRNA molecules that encode no proteins and are entirely dependent on the host for replication. For up to date information on the taxonomy of plant-infecting RNA viruses, which is changing constantly, and their relationships to other virus types, the reader is referred to the Universal Virus database of the International Committee on Taxonomy of Viruses, the ViralZone website and the Association of Applied Biologists Descriptions of Plant Viruses (websites listed under *Further Reading*).

General Characteristics of Plant-Infecting RNA Viruses

History

Viruses were discovered first in plants and the ‘first’ virus, named tobacco mosaic virus (TMV) by Beijerinck in 1898, is a positive-sense ssRNA virus that has been used extensively for over a century as a model for the investigation of many important

concepts in modern biology. These concepts include the elucidation of the genetic code, the mechanisms of protein synthesis, and the mechanisms of self-assembly of biological macromolecular structures. More recently, TMV and other plant viruses have been engineered for use as gene expression vectors in plants or as reaction vessels, substrates and scaffolds for nanotechnology.

Transmission

Over 70% of plant viruses are transmitted (vectored) by invertebrates. Insects with probing/sucking mouthparts (stylets) such as aphids and close relatives (whiteflies, leafhoppers, planthoppers, etc.) vector the most viruses, with a small number being vectored by chewing insects, such as beetles, or other arthropods such as mites and ticks. Dagger-type nematodes (those feeding on plants using a stylet) belonging to the order *Dorylaimida* transmit members of two genera of positive-sense RNA viruses: *Nepovirus* and *Tobravirus*. A number of positive-sense RNA viruses are transmitted on the zoospores (motile spores) of soil-living organisms often referred to as 'fungi' that are, strictly speaking *Plasmodiophoromycetes*. Zoospores of *Olpidium* species transmit viruses with icosahedral particles (for example *Tobacco necrosis virus* and *Satellite tobacco necrosis virus*, STNV), while those of *Polymyxa* species transmit rod-shaped viruses such as *Soilborne wheat mosaic virus* or *Beet necrotic yellow vein virus*. Some RNA viruses [e.g., TMV, *Potato virus X* (PVX)] and viroids have no known vectors but are known to be mechanically transmissible (i.e., entering the plant through wounds and abrasions). These agents, as well as those with known biological vectors, can in many instances also be transmitted through plant material via grafts or as a result of infestation with dodder (*Cuscuta* spp.: A parasitic plant). In certain cases, vertical (inter-generational) transmission can occur through seed or pollen.

Broadly, there are two types of interaction between viruses and their biological vectors. Viruses may be taken up internally by the vector (circulative transmission) or carried on the exterior of the vector, for example on the mouthparts of invertebrate vectors (non-circulative transmission). The majority of insect-vectored positive-sense RNA viruses are transmitted in a non-circulative fashion and the key viral gene product facilitating binding of virus particles to the vector mouthparts is the viral coat or 'capsid' protein (CP). The CP is the sole determinant of transmission for many viruses, for example *Cucumber mosaic virus* (CMV). However, certain viruses encode proteins called helper factors that are not required for virus particle assembly but that are required to bind the virus particle to the vector. The helper component/protease (HC-Pro) proteins encoded by potyviruses bind a specific three amino acid domain on the viral CP and act as a bridge to link the particle to the stylet of the aphid vector.

During circulative transmission of viruses by insects virions are ingested, cross the gut wall into the hemolymph (circulatory fluid), and are transported into the salivary glands. No plant positive-sense RNA viruses are known to replicate in the cells of their insect vectors but several negative-sense and dsRNA viruses do. Aphids and closely-related insects possess specialized cells that harbor bacterial endosymbionts (*Buchnera* species). These bacteria release symbionin, a homolog of the *Escherichia coli* chaperonin, GroEL. Symbionin interacts with and protects the particles of circulatively transmitted viruses, allowing the safe passage from gut to salivary gland of viruses that cannot replicate in the insect. This allows transmission of circulatively transmitted positive-sense RNA viruses, for example the luteoviruses and poleroviruses.

Spread Through Host Plants

In contrast to viruses infecting many other types of organism, plant viruses do not need to physically break out of one host cell in order to invade the next. This is because most cells within a plant are linked symplastically by a local network of intercellular cytoplasmic connections (plasmodesmata). Plasmodesmata are dynamic, structures with the ability to regulate the selective cell-to-cell trafficking of various small and large molecules. This local system of cell-to-cell connections has links with the cells of the phloem. The phloem is a network of living vascular cells that conduct sugars and other more complex molecules, including RNA and protein molecules, over longer distances through the plant. Thus, in principle, the virus has access to nearly all parts of a host plant.

Cell-to-cell movement through plasmodesmata is relatively slow and is mediated in most cases by viral movement proteins. Movement proteins fall into two broad types. The first type, exemplified by the tobacco mosaic virus (TMV) movement protein, facilitates cell-to-cell transfer of viral nucleic acids by interacting with host factors to increase the permeability of the plasmodesmata and by unfolding the secondary structure of the viral nucleic acid. The second type of movement protein, exemplified by that of *Cowpea mosaic virus* (CPMV), forms tubules. These tubules obliterate the internal plasmodesmal structure and are wide enough to allow passage of entire viral particles. In some cases (for example closteroviruses and potyviruses) it appears that protein components of the virion or non-structural viral proteins associated with virus particles *in vivo* can facilitate the binding of virus particles to plasmodesmata. Subsequently viral RNA is transferred by a process in which ribosomes of the receiving cell translate viral RNA into protein and co-translationally pull the RNA in through the plasmodesmata. For viroids, which encode no proteins, the secondary structure of the viroid RNA in some way facilitates movement through plasmodesmata.

Double-Stranded RNA Viruses

In plants, the dsRNA viruses that are infectious and which cause recognizable diseases are members of the *Reoviridae*, which possess segmented genomes (10 or 12 dsRNA components). The other known plant-infecting dsRNA viruses are the 'cryptoviruses' and endogenous RNA viruses (*Endornaviridae*). Cryptoviruses belong to genera of the *Partitiviridae*, which have genomes consisting of

two dsRNA segments (Table 1). The cryptoviruses are transmitted vertically (i.e., through pollen/seed) and the majority having no other known mode of transmission. Virtually none of the cryptoviruses are known to induce disease in their host plants. Endornaviruses are also horizontally transmitted but have monopartite dsRNA genomes. Their genomic dsRNA molecules are associated with the viral RNA-dependent RNA polymerase (RdRP) but are not encapsidated in virions.

The Family *Reoviridae* contains a large number of viruses infecting vertebrates, insects, and plants. There are three genera of plant-infecting reoviruses. Members of the genus *Phytoreovirus* (for example *Wound tumor virus*: WTV) have genomes consisting of 12 dsRNA segments and most are vectored by leafhopper insects. WTV was the first plant virus demonstrated to be able to replicate in the cells of its insect vector. Viruses in the genus *Fijivirus* (Type species: *Fiji disease virus*, a pathogen of sugarcane) and *Oryzavirus* (e.g., *Rice ragged stunt virus*) possess 10 segment genomes and are transmitted, respectively, by planthoppers and leafhoppers.

Reovirus virions are double-layered isometric particles each containing a complete set of genome segments. The inner shell or 'core' contains the RdRP required for genome replication and the transcription of viral mRNAs. Replication occurs in the cytoplasm of the host cell (plant or insect) with new genomic dsRNA being formed within the cores of nascent virus particles. The ends of each genome segment contain virus-specific and segment-specific sequence tags that ensure that each new virion contains the appropriate complement of 10 or 12 genomic dsRNA segments.

Negative-Sense Single-Stranded RNA Viruses

Most known plant-infecting viruses possessing negative-sense linear ssRNA belong to the families *Rhabdoviridae* and *Bunyaviridae*. Both of these families include viruses infecting vertebrates. Other plant-infecting negative-sense RNA virus genera include *Tenuivirus* (type species: *Rice stripe virus*), *Ophiovirus* (type species: *Citrus psorosis virus*) and *Varicosavirus* (type species: *Lettuce big-vein virus*) among others (Table 1).

Rhabdoviruses have the largest virions among viruses infecting higher plants. Rhabdovirus virions are bullet-shaped or bacilli-form particles and contain one genomic RNA molecule, between 11 and 13 kilobases in length, which is associated with a protein, N, to form a nucleocapsid core. A lipid membrane envelops this core, together with several other viral proteins, including the viral RdRP. The genomic RNA molecules of plant-infecting rhabdoviruses are distinguished from those unable to infect plants by encoding a cell-to-cell movement protein in addition to the five proteins required for replication and assembly. The negative-stranded RNA can function as a template for a full-length complementary copy that serves as an intermediate in replication and for the transcription of subgenomic mRNAs. Rhabdovirus replication occurs in either the nucleus (nucleorhabdoviruses e.g., *Sonchus yellow net virus*) or cytoplasm (cytorhabdoviruses e.g., *Lettuce necrotic yellows virus*) of the host cell. Plant-infecting rhabdoviruses can replicate in the cells of their vector insects, which may be aphids, planthoppers or leafhoppers. In general, rhabdoviruses infecting monocotyledonous hosts are transmitted only by planthoppers and leafhoppers.

Tospoviruses, tenuiviruses, ophioviruses and varicosaviruses possess segmented ssRNA genomes. Some of the genome segments of tospoviruses and tenuiviruses are ambisense. That is, these RNAs encode more than one protein by having one negative-sense and one positive-sense open reading frame. However, neither protein can be expressed directly using the genomic RNA as a translation template and protein synthesis occurs from subgenomic RNAs. Tospoviruses and tenuiviruses initiate transcription of their mRNAs by 'cap snatching', which is the removal of cap structures and up to 20 nucleotides from molecules of cellular mRNAs, or even the RNAs of other viruses, to use as primers of RNA-directed RNA synthesis. In the tospovirus life cycle the level of the N (nucleocapsid) protein regulates the switchover in L protein (RdRP) activity from mRNA transcription to replication of the genomic RNAs.

Tospoviruses are plant-infecting members of the family *Bunyaviridae*, which also includes a larger number of vertebrate-infecting viruses. The type species of the *Tospovirus* genus is *Tomato spotted wilt virus* (TSWV), which has a large host range (in excess of 600 plant species) and is transmitted by thrips, in which it also replicates. The TSWV genome comprises three ssRNAs: one negative-sense and two ambisense RNAs. TSWV virions contain one copy of each of the three genomic RNAs complexed with N protein and L proteins contained within a spherical lipid envelope. These plant-infecting bunyaviruses are distinguished from their vertebrate-infecting relatives by encoding a tubule-forming movement protein, NS_M.

Positive Sense Single-Stranded RNA Viruses

The RNA genomes of these viruses contain open reading frames in the sense orientation and consequently can serve directly as mRNAs for synthesis of at least some of the proteins they encode. In many cases, RNA purified from virions is infectious and can be used to program *in vitro* protein synthesis systems. Typically, replicase protein(s) can be synthesized by translation of the genomic RNA on host ribosomes. Consequently, the virions of positive sense RNA viruses do not contain viral RdRP. Generally, the virions of plant-infecting positive sense RNA viruses are constructed more simply than those of dsRNA and negative-sense ssRNA viruses, or compared with many positive sense RNA viruses infecting non-plant hosts. The majority of plant-infecting positive sense RNA viruses possess virions with shells formed from one or two types of CP molecule, with simple geometries based on the rod or icosahedron.

About two-thirds of the known species of plant infecting positive-sense RNA viruses are classified into seven families, with the remainder unassigned (Table 1). Most of these viruses encode a small number of polypeptides (typically between four and eleven). However, satellite viruses encode only one protein (the CP). Satellite viruses are hyper-parasitic upon another, unrelated virus

(the helper) for replication. Satellite viruses should not be confused with satellite RNAs, which are sub-viral, hyper-parasitic RNA molecules that are dependent on a helper virus for replication and encapsidation, and often do not possess any protein coding information. The presence of satellite viruses and satellite RNAs can modify the symptoms induced by a helper virus and affect the helper's titer in host tissue.

Genomic RNA molecules range in length from 1240 (e.g., STNV) to 20,000 nucleotides (e.g., the *Closterovirus Citrus tristezza virus*). The genomes of many plant-infecting positive sense RNA viruses are multipartite, comprising two or more mono- or multi-cistronic RNA segments. However, in contrast to negative sense ssRNA and dsRNA viruses with segmented genomes, which encapsidate an entire set of genomic RNA molecules in the same virion, the genome segments of positive sense RNA viruses are encapsidated in separate particles.

Viral RNA molecules possess various virus-specific 'non-coding' nucleotide sequences or structural features that enable particular viruses to replicate or express their genes. These sequences and structural features may act as promoter sequences for synthesis of full-length or subgenomic RNAs; they may facilitate the interaction of viral RNA with the cellular protein synthesis machinery, or they may have additional functions, such as promoting the interaction of viral RNA with CP during virion assembly. Structural features in these viral RNAs arise by folding and internal hybridization of complementary nucleotide sequences or by the covalent attachment of additional chemical moieties following transcription.

Virus-specific structural elements in the RNA of positive sense RNA viruses include tRNA-like structures occurring at the end of the 3' untranslated region (3'-UTR) of some viruses (e.g., species in the genera *Tobamovirus*, *Cucumovirus*, *Bromovirus*). These 3'-tRNA structures can be aminoacylated with an amino acid specific to the virus but their role appears to be in translation of viral RNA. tRNA-like structures and other complex folding arrangements occur when nucleotide sequences on the loop of a stem-loop base-pair with complementary sequences outside the loop, forming pseudoknots. These can play roles in the regulation of viral gene expression and RNA synthesis.

The 5'-UTRs perform an important role in facilitating translation of viral RNA by the host cell ribosomes and may contain sequences that enhance translation of viral RNA, presumably to out-compete cellular mRNAs for access to the translation machinery. One of the best-studied translational enhancers is the Ω sequence of TMV RNA: a 68 nucleotide long leader containing a 25 nucleotide poly (CAA) sequence that enhances the initiation step of translation. *In vitro* studies indicate that enhancement of translation is mediated by binding of the heat shock protein HSP101 and the initiation factor eIF4F to Ω . However, it is unclear if the HSP101 is an absolute requirement for enhancement *in planta*. 5'-UTRs with similar translational enhancer properties have also been identified for PVX and alfalfa mosaic virus.

Post-transcriptional modifications of viral RNA include the addition of a 7-methyl guanosine triphosphate cap structure to the 5' terminus of the molecule. This simulates a modification common to the majority of cellular mRNAs in a eukaryotic host and increases the translational efficiency and stability of the viral RNA. Viruses with capped RNAs often encode a replicase protein with methyltransferase (RNA capping) activity (e.g., species in the genera *Tobamovirus*, *Cucumovirus*, *Bromovirus*). The genomic RNAs of certain viruses, for example the potyviruses, are modified at the 5' end by the covalent addition of a virus-encoded protein called the VPg (virus protein, genome-linked). The VPg can fulfill a similar role to the cap in the initiation of translation by interaction with host translation factors, particularly variants of eukaryotic initiation factors (eIF) 4E and eIF(iso)4E. Following virion formation, VPg projects from the end of these filamentous virus particles allowing interactions with HC-Pro (the helper factor in aphid transmission) and, potentially, the plasmodesmal pores to initiate cell-to-cell movement. Potyviruses are also an example of a virus type that is modified on the 3' end of its genomic RNA by the addition of poly(A) tracts. These are a feature of the 3'-termini of most cellular mRNAs. These enhance the efficiency of translation and in viruses influence replication and RNA stability.

Replication of Positive Sense RNA Viruses

Composition and Assembly of the Replicase Complex

All known plant-infecting RNA viruses, with the exception of satellite viruses, encode one or more enzymes that function in the synthesis of viral RNA. Replication of positive-sense RNA viruses is carried out in the cytoplasm of the host cell by a replicase complex, which possesses RdRP activity. Replicase complexes also possess helicase activity, in order to separate nascent RNA strands from template RNA and may also possess other, virus-specific, activities (e.g., methyltransferase activity for addition of 5'cap structures to nascent RNA).

Positive-sense RNA virus replicase complexes contain proteins encoded by the virus and the host cell. Active preparations of the CMV and *Brome mosaic virus* (BMV) replicase complexes have been purified and both preparations contained two virus-encoded proteins and one host protein. The nomenclature used to describe the proteins encoded by BMV and CMV is very similar and in both cases these proteins are called 1a (c. 110 kDa proteins possessing methyltransferase and helicase activities) and 2a (c. 90 kDa proteins with RdRP activity). The CMV complex was found to contain a host protein (c. 50 kDa) of unknown identity and the BMV complex is associated with a protein related to a subunit of the translation factor eIF3. A membrane-associated preparation of the TMV replicase was found to contain the two TMV-coded replicase proteins. The 126 kDa (methyltransferase and helicase) and 183 kDa (methyltransferase, helicase and RdRP) proteins are associated in the viral replicase complex as heterodimers. At least one host-coded protein of unknown identity has been found in replicase extracts.

The replicase complexes of positive-sense RNA viruses assemble on the host cell's intracellular membranes. Ishikawa and colleagues (Tokyo) identified and analyzed mutant lines of the plant *Arabidopsis thaliana* that were unable to support the replication

of TMV. They identified the protein products of the genes that had been mutated in some of these lines. These proteins, called TOM ('tobamovirus multiplication') 1, 2A, 2B and 3 all proved to be transmembrane proteins that interact with each other and/or the helicase domain common to the TMV 126 and 183 kDa replicase proteins, functioning to anchor the replicase complex to the ER and/or the vacuolar membrane of the host cell.

Some of the most revealing insights on the interactions of viral replicase complexes with host cell membranes and other host factors have emerged from the work of P. Ahlquist and colleagues (Madison, Wisconsin) and of P. Nagy (Kentucky). These groups have made extensive use of yeast, a highly developed genetic model organism, to identify cellular genes required for viral replication. Mutagenesis of transformed yeast lines expressing the viral replicase proteins and harboring replicons (replicating RNA molecules) derived from BMV or tombusviruses revealed that virus replication is dependent on the action of multiple cellular genes. For example, proper association of viral replicase proteins with host cell membranes is sensitive to membrane composition and thus mutations in yeast genes encoding specific lipid biosynthetic enzymes (e.g., $\Delta 9$ fatty acid desaturase) inhibited replication of a BMV-derived replicon.

Further work using transformed yeast cells showed that the BMV replicase complex induces lipid synthesis and remodels the membrane to form simple-to-complex invaginations with an open 'neck' to the cytoplasm in which viral RNA synthesis takes place. The complexity of these invaginations is controlled by the relative proportions of the BMV 1a and 2a proteins (Fig. 1). Ahlquist has speculated that the synthesis of nascent viral RNA in these membrane invaginations by positive-sense RNA viruses is a functional analogue of RNA synthesis in nascent virions or virion cores by negative-sense and dsRNA viruses. The enclosure of RNA synthetic activity in open membrane vesicles or in virions provides benefits including: the concentration of replication proteins, RNA templates and substrates; the linkage of successive steps in replication by keeping replicase components and RNA intermediates in close proximity, and the sheltering of template RNA, nascent viral RNA, and replication intermediates from the RNA silencing machinery of the host (see 'Mechanisms of pathogenesis').

The primary function of the replicase complex is to generate identical copies of the full-length genomic RNA (Fig. 2). The RdRP component of the viral replicase complex recognizes the sequences and/or their folded secondary structures (see 'Positive sense single-stranded RNA viruses') at the 3' end of the genomic RNA (plus-sense) as a promoter.

In general, for plant-infecting positive sense RNA viruses, initiation of RNA polymerization occurs *de novo*, without any need for an oligonucleotide or a protein primer. However, some purified RdRPs can utilize a short primer *in vitro*. The helicase activity of the complex unwinds and separates the template and nascent RNA strands. The RdRP can use either the released plus-sense genomic RNA to synthesize more minus-sense RNA or it can use the minus-sense RNA as template for synthesis of plus-sense viral RNA (Fig. 2). The replication process is biased in that much more positive sense than minus sense RNA is made. Current thinking is that this bias is controlled by inhibitory 'silencer' sequences in the positive strand, not by the relative strength of the minus and plus sense promoters.

For some viruses the replicase has a secondary role, which is in the transcription of shorter than full-length subgenomic RNA molecules that may function as mRNAs. For most plant-infecting positive sense RNA viruses the synthesis of subgenomic RNA probably occurs by initiation of RNA synthesis at an internal promoter sequence on the full-length minus-sense RNA replication intermediate (Fig. 2). Examples of viruses using this approach to subgenomic RNA synthesis include BMV, CMV and TMV. For certain other plant-infecting positive sense RNA viruses, templates for subgenomic RNA synthesis are formed by premature

Fig. 1 Models for rearrangements of host cell intracellular membrane by the replication proteins 1a and 2a of Brome mosaic virus. Infection of cells with positive-sense RNA viruses is often accompanied by the re-shaping of intracellular membranes. Based on experiments with BMV, Ahlquist and colleagues argue that the formation of vesicles provides an environment conducive to efficient replication and protection against host defenses. In this diagram bold lines and gray shading represent ER membranes and ER lumen, respectively. (A) Invagination of a spherule (50 nm in diameter) into the outer perinuclear ER membrane by 1a. Formation of a membrane-enveloped, capsid-like shell occurs by 1a-mediated recruitment of 2a (the RNA polymerase) and viral RNA. (B) High 2a concentrations may promote zippering together of double-membrane layers by 1a–2a complexes. Replication factor 1a might participate as monomers or multimers (hexamers or pentamers). Self-interaction of 2a might be direct or mediated by RNA or 2a-interacting host proteins. (C) High 2a^{pol} concentrations may block 1a–1a curvature needed to form spherules by steric hindrance between 2a factors bound to adjacent 1a factors (left side), tending to restrict 1a to planar lattices (right side). (D) Between the stacked double-membrane layers, extended planar lattices of 1a with bound 2a might provide a local replication complex environment similar to spherule interiors and may be closed by occasional regions of 1a curvature. Adapted from Schwartz, M., Chen, J., Lee, W.M., Janda, M., Ahlquist, P., 2004. Alternate, virus-induced membrane rearrangements support positive-strand RNA virus genome replication. *Proceedings of the National Academy of Sciences of the United States of America* 101, 11263–11268.

Fig. 2 Replication and transcription of sub-genomic RNAs by positive-sense RNA viruses. Panel (A) depicts the genome of an archetypal plant-infecting positive-sense RNA virus with two open reading frames shown for a replicase protein (solid gray box) and the coat protein (hatched box). The replication of full-length genomic RNA. (B) The genomic RNA serves as the template for synthesis of a full-length complementary-sense RNA molecule. The 5'–3' synthesis of the complementary RNA by the RNA-dependent RNA polymerase (RdRP) activity of the viral replicase initiates following recognition of a promoter sequence at the 3' terminus of the genomic RNA (indicated by a star). The helicase activity of the replicase separates the nascent strand from the template RNA. The full-length complementary RNA is the template for synthesis of new full-length genomic RNA molecules, following recognition by the replicase of a promoter of positive-sense RNA synthesis at the 3' terminus (indicated by a diamond). Among plant-infecting positive-sense RNA viruses that express subgenomic RNAs to serve as mRNAs for nested open reading frames (such as that encoding the coat protein in this example), the majority transcribe them by initiation of positive-sense RNA synthesis at an internal promoter sequence (indicated with a triangle) within the full-length complementary RNA. (C) In some cases, transcription of sub-genomic RNA utilizes a less-than-full-length complementary-sense RNA generated by premature termination of copying of the genomic RNA. (D) Premature termination (indicated by a lightning bolt) is usually facilitated by interactions between viral RNA sequences on the same strand (*cis*-interactions) or on separate strands (*trans*-interactions) of virus-derived RNA.

termination of minus-strand synthesis (Fig. 2). Premature termination at a specific point on the minus strand is fostered by interactions between sequences within the same RNA strand (*cis* interactions: suggested for subgenomic RNA synthesis by PVX and *Tomato bushy stunt virus*) or by interactions between different RNA segments of multipartite viruses (*trans* interactions: e.g. the *Dianthovirus Red clover necrotic mosaic virus*).

Viral Gene Expression

Virtually all mRNAs in eukaryotic cells are monocistronic i.e. they encode a single polypeptide. For the majority of cellular mRNAs translation begins with the attachment of the 40S ribosomal subunit to the cap structure. This 'scans' in a 5' to 3' direction until it reaches an AUG codon. In eukaryotic cells, the likelihood of translation initiating at any given AUG depends on the sequences immediately flanking it. For example, a sequence context that makes an AUG a 'strong' translational start is 5'-. . .AXCAAUGG. . .3', where X is a purine and the translational start is italicized. At the translational start 80S ribosome assembly is completed and protein synthesis commences. Protein synthesis ceases once the ribosome reaches a termination codon. Although circularization of eukaryotic mRNAs allows ribosome subunits to be recycled back to the initiation codon (see 'Interactions of viral mRNAs with the cellular translational apparatus'), re-initiation of translation from downstream ORFs will not normally occur and any sort of internal initiation of translation is extremely rare. The characteristics of the eukaryotic translation system pose significant challenges to viruses, which often encode multiple proteins on the same RNA molecule. Viruses have evolved gene expression strategies, used in various combinations, to evade or exploit the constraints of the cellular translation machinery.

Strategies Used to Overcome the Constraints of Eukaryotic Translation

Around half of the known plant-infecting viruses possess multiple genome segments. The division of genomes in this way can give directly translatable RNAs with an open reading frame adjacent to the 5' end of the RNA (many positive sense RNA viruses e.g., BMV, CMV) or provide a template for a monocistronic mRNA (e.g., reoviruses). The generation of subgenomic RNAs

provides a means of expressing open reading frames that would otherwise be in an unsuitable context for translation due to orientation (e.g., tospoviruses, reoviruses) or placement within a positive sense RNA molecule downstream of a 5'-proximal open reading frame. For example, the RNAs 3 of BMV and CMV can be used directly as translation templates for synthesis of their respective movement proteins. However, in both viruses the open reading frame for CP, which is also on RNA3, is downstream of the movement protein open reading frame, and translation of CP occurs from a subgenomic RNA on which the CP open reading frame is proximal to the 5' end.

Some viruses avoid the problem with re-initiation of translation by generating two versions of a protein, one shorter protein initiated from the 5' proximal start codon, or a longer fusion protein in which the shorter protein constitutes the N-terminal domain. This can be achieved either by inhibiting the termination of the synthesis of the shorter protein ('read-through'), or by shifting the frame of translation before a stop codon is reached ('frame-shift'). TMV offers the best-studied example of read-through translation. The 5'-proximal open reading frame on the genomic RNA of TMV encodes the 126 kDa replicase protein. In up to 10% of translation rounds, the ribosome fails to detect the UAG stop codon of this open reading frame and elongation of the nascent polypeptide continues in-frame to yield the 183 kDa replicase protein. The effect is permitted by the existence of 'suppressor' tRNAs: tRNAs that can misread a stop codon. In tobacco there are two tyrosine tRNAs that possess the anticodon sequence G-pseudouridine-A and which can suppress termination of synthesis of the 126 kDa protein. However, the nucleotide sequence immediately flanking the UAG codon, i.e. its sequence context, determines the efficiency of read-through and mutations in the flanking sequences decrease the rate at which read-through occurs.

Frame-shifting allows a ribosome to avoid a stop codon at the end of an open reading frame by sliding forward or back by one nucleotide. The switch into the +1 or -1 reading frame allows further translational elongation and generation of a longer fusion protein. As with read-through, translation proceeds normally and without shifting in the majority (90%–95%) of ribosome passes and sequence context of the shift site is important in determining the rate at which frame-shifting occurs. The shift site itself is sometimes termed a 'slippery' site and its shifting activity is further modified by the folding of adjacent RNA sequences into stem-loop and pseudoknot structures. Examples of plant-infecting RNA viruses using frame-shifting include BYDV (-1 shift) and the *Closterovirus Beet yellows virus* (+1 shift). Both of these viruses utilize frame-shifting in translation of replicase proteins.

Viruses belonging to species within the *Potyviridae*, *Comoviridae* and a number of other virus taxons synthesize polyproteins from monocistronic genomic RNAs. A polyprotein is a precursor polypeptide that is broken down by selective proteolysis to yield the mature viral structural proteins (constituents of the virion) and non-structural proteins. The majority of the *Potyviridae* are monopartite RNA viruses that encode a single polyprotein, while viruses within the *Comoviridae*, which have two genomic RNAs, give rise to two polyproteins. Self-processing of the polyprotein has been studied in detail in species of the genus *Potyvirus* (e.g., *Potato virus Y*, *Tobacco etch virus*). Potyviral RNA contains a single open reading frame that is translated to yield an approximately 330 kDa polyprotein. This is processed by three proteinase active sites located within the nascent polypeptide to yield the majority of mature viral proteins. The potyviral proteinases are: The P1 serine proteinase that cleaves only *in cis*; the HC-Pro, which has cysteine proteinase activity but cleaves only *in cis*, and the 27K Pro, which is a serine proteinase that can carry out *cis* and *trans* cleavage.

Recently, bioinformatic analysis of collected sequences of the *Potyviridae* and deep sequencing analyses of the products of viral RNA synthesis in plants infected with these viruses revealed an additional form of gene expression for (+) sense RNA viruses. During (+) strand synthesis from the (-) strand template, the potyviral RdRP slips at specific sequence to yield a small number of molecules that are a variant of the viral RNA that can act as the translation template for a potyviral movement protein. Sweet potato – Infecting potyviridae also employ transcriptional slippage to generate the template for translation of a suppressor of RNA silencing.

Other, less common strategies include leaky scanning in which two potential translation start sites occur proximal to the 5' end of an RNA, where the first AUG is in a usable but not particularly strong sequence context, allowing a proportion of scanning 40 S ribosomal subunits to pass by and detect a downstream AUG. These potential sites may be in-frame with each other. An example of this is in the translation of alternative in-frame polyproteins from the shorter of the two genomic RNAs of CPMV. In some cases two out-of-frame AUG codons generate overlapping ORFs, allowing a single RNA molecule to act as a mRNA for two distinct polypeptides, a strategy utilized by BYDV for proteins encoded by its open reading frames 3–4. Internal ribosome entry sites (IRESs) are sequences within the RNA molecule that allow binding of ribosomes without scanning and play an important part in allowing certain animal viruses, notably the picornaviruses, to evade the constraints of ribosomal scanning. However, apart from reports of potential IRESs in certain strains of TMV, and in small number of other examples (the *Carmovirus Hibiscus chlorotic ringspot virus* and the *Nepovirus Blackcurrant reversion virus*) internal initiation does not appear to play a widespread role in gene expression among plant-infecting RNA viruses.

Interactions of Viral mRNAs With the Cellular Translational Apparatus

Eukaryotic mRNA is normally translated in a circularized form (Fig. 3). Sub-components of the eIF4 complex form a bridge between the 5' cap structure of the mRNA and poly(A) binding protein (PABP) bound to the 3' tail. This circularization enhances the efficiency of translation by re-cycling 40S ribosomal subunits back to the 5' end of the mRNA. There are viruses with genomic RNAs that possess 5' cap structures and 3' tails (a small number of positive sense RNA viruses e.g., *Beet necrotic yellow vein virus*) or which give rise to subgenomic mRNAs that possess these features (e.g., dsRNA and negative sense RNA viruses). These RNAs effectively mimic cellular mRNAs and can circularize during translation. However, many plant-infecting positive sense RNA viruses lack a 5' cap and most do not possess a 3' poly(A) tail.

Fig. 3 Interactions of positive-sense RNA viruses with the translation machinery of the plant cell. Cellular mRNAs undergoing translation can be circularized due to interactions between the 3' poly(A) tail with poly(A)-binding protein (PABP: Indicated by a triangle) and between PABP and subunits of eukaryotic initiation factor 4 (eIF4: Indicated by ovals) bound to the cap structure 5' terminus of the mRNA. (A) This arrangement enhances the rate of protein synthesis by facilitating recycling of 40S ribosomal subunits to the 5' end of the mRNA. Viral RNAs can exploit this circularized mode by possessing 5' cap structures or 3' poly(A) tails, or by possessing other features that allow interaction with host components. For example, the VPg (viral protein genome-linked) of potyviruses, and members of several other groups of plant-infecting viruses, interact with certain eIF4 subunits. (B) However, viruses with RNAs that lack any ability to interact with eIF4 or PABP (e.g., *Barley yellow dwarf virus*) can enhance the rate of cap- and poly(A)-independent translation through circularization by self-interaction between complementary sequences on stem loops proximal to the 5'–3' termini (C).

Translatable viral RNA molecules that lack a 5' cap or 3' poly(A) tail possess various combinations of structural features to allow them to associate with PABP and the eIF4 complex and become circularized during translation. Viral RNAs lacking both structures can be translated efficiently due to the presence of translational enhancer sequences within the 5'- and 3'-UTRs. In the example of the *Luteovirus Barley yellow dwarf virus* (BYDV) W.A. Miller and colleagues (Iowa State University) showed that these translational enhancer sequences fold, forming so-called kissing stem-loops. Base-pairing between complementary RNA sequences in the loops allows circularization of the RNA molecule (Fig. 3). For viral genomic and subgenomic RNAs with 3'-tRNA like structures, such as TMV, pseudoknot structures within or immediately upstream of the tRNA-like structure can substitute for a 3' poly(A) tail. The binding of host factors such as HSP101 may aid in bridge formation between the upstream pseudoknots and the cap structure and Ω sequence at the 5' end of the RNA molecule but work in mutant arabidopsis plants suggests that this interaction may not be vital for a successful infection. Around a third of species of plant-infecting positive sense RNA viruses encode VPg proteins. As mentioned in the section titled 'Positive-sense single-stranded RNA viruses', a VPg can functionally substitute for a 5' cap structure by binding to subunits of eIF4, allowing bridging to occur to the PABP bound to the viral RNA 3' poly(A) tail (e.g., potyviruses: Fig. 3).

Mechanisms of Pathogenesis

Models of Pathogenesis: Competition for Host Resources *Versus* Specific Virus-Host Interactions

Plant RNA viruses elicit a diverse range of disease symptoms that vary dramatically between viruses and between virus strains. In the context of agriculture and horticulture, viruses are responsible for around 30% of the pathogen-induced diseases that cause significant losses in crop yield or quality. Their impact on crop production is likely to increase over time as around 45% of novel or emerging diseases appear to have a viral etiology.

In most plant–virus interactions in which the host is susceptible to infection, death of the host does not occur. Given that plant viruses can move from cell to cell through plasmodesmata (see 'Spread through host plants'), there would be no advantage to the virus in inducing lysis of host cells. The occurrence of host cell death is often an indication of resistance, or attempted resistance, to the virus.

It might be assumed that viral disease symptoms occur because a virus competes for and to some extent exhausts the resources of its host cells. However, in the majority of examples this model proved to be overly simplistic. For many virus-plant interactions the pathogenicity of a particular virus strain depends much more upon the qualities of one or more specific viral protein or nucleic acid sequences rather than upon any correlation with the quantity of virus that is produced during infection. Thus, mild and severe strains of the same virus often achieve the same titer in host tissues.

In recent years, major advances have been made in the identification of viral and host factors involved in pathogenesis. For example, it has been found that suppression of host defense mechanisms, particularly of those based on RNA silencing, is important

for the success of infection. RNA silencing is a mechanism, universal among eukaryotes, in which small RNAs direct the sequence-specific cleavage of target RNAs. One of the functions of this homology-based destruction of RNA is to contribute to host resistance to viruses by limiting or preventing the accumulation of viral RNAs (see 'Viral counter-defense: RNA silencing and its suppression by viruses'). Recent advances have shown that it is the dynamic interplay between host RNA silencing pathways and viral counter-defense factors that engender many common viral disease symptoms in plants.

Cytological Changes

Electron microscopy reveals striking changes in cellular ultrastructure resulting from virus infection. These include changes in cellular membrane morphology associated with assembly of positive-sense RNA virus replication complexes (see 'Composition and assembly of the replicase complex'). One of the first characterized examples of this was the interaction of the *Turnip yellow mosaic virus* (TYMV) replication machinery with the outer membrane of infected cell chloroplasts. In TYMV-infected cells the chloroplasts swell, aggregate, and adopt a cup-shaped form. Two TYMV proteins are involved in these processes, the 66–140 kDa proteins. Both are targeted to the chloroplast membrane. The 140 kDa protein induces chloroplast aggregation and also induces invagination of the outer chloroplast membrane to form small peripheral vesicles, which are the sites of TYMV replication (see 'Composition and assembly of the replicase complex').

Virus-infected cells may contain inclusions of virus-derived material, sometimes termed 'viroplasms'. Inclusions may be crystalline, quasicrystalline, or amorphous in appearance. They may result from the accumulation of nascent virions in the host cell. Some inclusions are aggregates of viral proteins. For example, the potyviruses use a polyprotein strategy to express most of their proteins ('Strategies used to overcome the constraints of eukaryotic translation'). As a result, certain viral proteins are produced in excess of need. The surplus proteins form nuclear inclusion bodies, composed of the nuclear inclusion (NI) proteins NIa and NIb, and cytoplasmic bodies, formed from aggregated cylindrical inclusion (CI) protein. Cytoplasmic bodies sometimes display 'pinwheel' morphology. Other inclusion bodies may represent the sites of active replication associated with nascent virions in the cytoplasm or nucleus (e.g., cyto- and nucleorhabdoviruses, respectively) or virion core structures (e.g., reoviruses).

Macroscopic Symptoms: Mosaics and Vein Clearing Symptoms

Among the most common, visible virus symptoms on the younger, developing leaves of systemically-infected plants is the generation of mosaic or stripe patterns (Fig. 4). These patterns are formed from discrete regions of chlorotic (yellow or light green) tissue surrounding or adjacent to healthy-appearing areas of darker green tissue, which are sometimes called dark green islands (DGIs). This patterning takes the form of a mosaic on dicotyledonous hosts or stripes on monocotyledonous hosts and reflects the respective patterns of cell division and expansion in these two groups of angiosperms.

The cells within DGIs exhibit cytology and photosynthetic capacity comparable to that of leaves of uninfected plants. Importantly, they contain much less virus than chlorotic areas and resist reinfection with the same or closely related viruses but not with unrelated viruses. Several lines of evidence indicate that DGI formation and maintenance is controlled by localized RNA silencing (for description of RNA silencing, see 'Viral counter-defense: RNA silencing and its suppression by viruses'). During infection of *Nicotiana benthamiana* with the potyvirus *Tamarillo mosaic virus* (TaMV), virus-specific transcripts were undetectable in DGIs. Prior systemic infection of plants with an asymptomatic, unrelated heterologous viral vector harboring a region of the TaMV genome, followed by superinfection with TaMV, resulted in reduced titers of both viruses in the DGIs. DGI formation in TMV-infected tobacco can be suppressed by a viral RNA silencing suppressor and by silencing of RNA-directed RNA polymerase 1 (RDRI), a component of the host RNA silencing machinery. Finally, high levels of short interfering RNAs (siRNAs) complementary to the infecting virus were detected in DGIs.

Fig. 4 Symptoms of TMV in tobacco (*Nicotiana tabacum*) leaves. Non-inoculated, systemic leaves of mock-inoculated and TMV (strain YSI/1) inoculated *N. tabacum* plants. Note mosaic patterning and vein-clearing in the infected leaves. Photographs supplied by S. F. Fu (University of Cambridge, UK).

In systemically-infected leaves of dicotyledonous hosts the cells bordering the veins become light green, yellow, or even white. This effect is known as vein clearing and often occurs before the establishment of mosaic symptoms. The precise cause of vein clearing is not fully understood and may differ between virus-host combinations. In her classic observations of virus-infected sugar beet, K. Esau noted that in plants infected with beet mosaic virus, the cells surrounding veins enlarge and their chloroplasts break down resulting in translucency. However, W. Dawson has observed that vein clearing induced by TMV occurs without chloroplast degradation and is seen only between 25°C and 40°C, seemingly due to host signaling since the phenomenon precedes viral invasion. The 'chlorotic' appearance of veins in TMV-infected tobacco is thus an optical illusion produced by a change in size and translucency of the surrounding cells.

Changes in Plant Metabolism

Virus infection can cause dramatic changes in photosynthesis, respiration, and the translocation of carbohydrates and other substances around the host plant. Chlorosis in virus-infected leaves can result from damage to chloroplasts resulting from inhibition of photosynthetic activity. Studies of TMV-infected tobacco plants by several laboratories suggest that chlorosis in these plants is caused by the uptake of viral CP by chloroplasts. R.N. Beachy's laboratory showed that the CP accumulates in the thylakoid membrane, where it disrupts photosystem II (the water-splitting reaction of photosynthesis), resulting in severe free radical damage to the organelle. Using isolated chloroplasts for *in vitro* studies, M. Zaitlin's laboratory showed that uptake of the CP did not exploit the host's normal pathways for protein import. Rather, it was a property of the CP, when it was assembled into multimeric disks (an intermediate structure in TMV virion assembly), that allowed it to be taken up spontaneously into the chloroplasts and subsequently into the thylakoid membrane. Work from this group, and the group of K. Lehto, demonstrated that a single amino acid in the CP determines the efficiency of its uptake into chloroplasts and the relative severity of chlorosis caused by different TMV strains.

Changes in photosynthesis, respiration and carbohydrate translocation often cause localized accumulation and depletion of starch, the main storage carbohydrate of most plants. A. Maule and colleagues showed by detailed examination of virus infection sites that this and other metabolic changes wrought by virus infection result from highly complex, dynamic and apparently organized changes in host gene expression, enzyme activity and physiology (e.g., photosynthetic activity) within cells in and around the infection site. However, it is still unclear what, if any, importance these changes in metabolism have in determining the outcome of a plant-virus interaction.

In plants, carbohydrate, typically in the form of sucrose, is translocated through the phloem elements. Translocation of this fixed carbon is vectorial, with sucrose moving from carbon source tissues to carbon sink tissues. Examples of carbon source tissues are photosynthetically active leaves or storage tissues undergoing mobilization of reserves (e.g., during seed germination), whereas carbon sinks include immature or rapidly growing tissues and storage organs during the development of seeds, tubers, and so on. The partitioning of carbohydrate between plant organs is a delicate and dynamic equilibrium that alters subtly as plant development moves from germination to vegetative growth, and on to senescence and flowering. Disruption of this process by virus infection results in deregulation of sink – source relationships and is caused primarily because of the effects of movement proteins (see 'Spread through host plants'). Studies with transgenic potato and tobacco plants expressing the TMV movement protein demonstrated that by enhancing the gating of plasmodesmata, fine control of carbohydrate partitioning was abolished resulting in inhibition of development in younger tissues and storage organs.

Disruption of Phytohormone Signaling

Virus infection can disrupt signaling mediated by plant growth substances, auxins and cytokinins, altering plant growth and development and causing striking symptoms including stunting and a wide range of developmental abnormalities. We now know that in some instances this can be caused indirectly, for example, by the interference with the regulation of turnover of specific mRNAs (e.g., those encoding auxin response factors: ARFs) by microRNA (miRNA) (see 'Viral counter-defense: RNA silencing and its suppression by viruses'). J. Culver and colleagues (University of Maryland) demonstrated a direct effect of a viral protein on hormone signaling. The phytohormone auxin is involved in a broad range of developmental processes and disruption of auxin signaling results in strong developmental phenotypes. In yeast two-hybrid studies, the TMV 126/183 kDa replicase protein was identified as an interactor with a number of auxin/indole acetic acid proteins (Aux/IAAs). Aux/IAAs bind to and inhibit the activity of ARFs, which are transcription factors that activate auxin-responsive genes. By binding Aux/IAAs, the TMV replicase protein deregulates auxin-responsive gene expression, inducing developmental abnormalities. A mutant TMV strain encoding a replicase protein defective in the Aux/IAA interaction induced milder symptoms, while silencing of the plant gene for the interacting Aux/IAAs caused uninfected plants to phenocopy some of the developmental symptoms seen in TMV-infected plants.

Viral Counter-Defense: RNA Silencing and its Suppression by Viruses

RNA silencing describes a number of interrelated mechanisms that regulate host gene expression, control transposons, and target the RNAs of invading viruses for degradation. The mechanisms are highly conserved between plants and animals. For detailed explanations, readers are directed to recent reviews (see Further Reading). In the case of host genes, silencing is effected by DNA

Fig. 5 Simplified schematic illustrating siRNA-mediated RNA silencing against viruses. RNA silencing is triggered by dsRNA formed during viral replication, as a consequence of viral gene expression or due to secondary structure. A number of viral silencing suppressors are depicted by dark gray ovals containing white lettering, at probable or confirmed sites of action (see *Further Reading*). Host-encoded components of the silencing machinery are depicted by light gray shapes containing black lettering. dsRNA is cleaved by DCLs 2, 3 and 4, yielding primary siRNA duplexes. The viral silencing suppressors p19 (encoded by tombusviruses), HC-Pro (encoded by potyviruses) and p21 (encoded by closteroviruses) interfere with silencing by binding siRNAs, whilst p38 (encoded by carmoviruses) is thought to suppress silencing by inhibiting siRNA production by DCL enzymes. Primary siRNA duplexes are methylated by HEN1 and bind to a RISC, whereupon the passenger strand is degraded, yielding a primary siRNA (or guide strand). The primary siRNA guides sequence-specific degradation of complementary (target viral) RNAs by an AGO protein, which is the only identified member of the RISC in plants. The viral silencing suppressor P0 (encoded by poleroviruses) operates by targeting AGO proteins for degradation, whilst the 2b protein suppresses silencing by directly binding the RISC. In the transitivity phase of silencing, the products of target viral RNA cleavage are used as templates by host RDRs 1 and 6 to synthesize dsRNA. The dsRNA is cleaved by DCLs 2 and 4 to generate secondary siRNA duplexes that are derived from regions beyond the primary cleavage site. RISC then conducts further sequence-specific degradation of the original target viral RNA, guided by the secondary siRNAs from the secondary siRNA duplexes. Adapted from Lewsey, M., Palukaitis, P., Carr, J.P., 2008. Plant-virus interactions: Defence and counter-defence. In: Parker, J., (Ed.), *Molecular Aspects of Plant Disease Resistance*. Oxford: Blackwell.

Fig. 6 Simplified schematic illustrating silencing of endogenous transcripts by miRNAs and tasiRNAs. Silencing mediated by miRNAs commences with transcription of a pri-miRNA from an endogenous *MIR* gene. A number of viral silencing suppressors are depicted by dark gray ovals containing white lettering, at probable or confirmed sites of action (see *Further Reading*). Host-encoded components of the silencing machinery are depicted by light gray shapes containing black lettering. Contained within the pri-miRNA is a miRNA sequence (thick dark gray line). The pri-miRNA folds back and is processed by the enzymes DCL1 and HYL1, which produces the smaller pre-miRNA. Cleavage of the pre-miRNA yields a miRNA duplex, containing the miRNA and its complementary miRNA*. The viral silencing suppressors p19 (tombusviruses), HC-Pro (potyviruses) and p21 (closteroviruses) interfere with miRNA-mediated silencing by binding miRNAs. The miRNA duplex is incorporated into a RISC, one component of which is an AGO protein, and the complementary miRNA* is degraded leaving the mature, single stranded miRNA. The mature miRNA targets the RISC against endogenous mRNAs in a sequence-specific manner, causing them to be cleaved or translationally repressed. As with siRNA-mediated silencing, the viral silencing suppressors P0 (poleroviruses) and 2b (cucumoviruses) target the AGO proteins (see legend to Fig. 6) in order to suppress miRNA-mediated silencing, and likewise tasiRNA-mediated silencing. Finally, miRNAs also target RISC against complementary, non-coding pri-tasi-RNA transcripts. Pri-tasi-RNA transcripts are transcribed from endogenous *TAS* genes and their targeting by RISC initiates dsRNA synthesis by RDR6 using the pri-tasi-RNA as a template. Phased cleavage is conducted by DCL4, which may be inhibited by the viral silencing suppressor p38 (carmoviruses), generating tasiRNA duplexes that are methylated by HEN1. tasiRNAs may also be targeted by the viral silencing suppressors p19, HC-Pro and p21. These duplexes are taken up into a RISC and the passenger strand is degraded, leaving the mature tasiRNAs. These are complementary to endogenous RNA and target them for endonucleolytic cleavage by the RISC. Adapted from Lewsey, M., Palukaitis, P, Carr, J.P., 2008. Plant-virus interactions: Defence and counter-defence. In: Parker, J., (Ed.), *Molecular Aspects of Plant Disease Resistance*. Oxford: Blackwell.

methylation of genetic loci, translational inhibition, and degradation of mRNAs, whereas RNA viruses appear to be silenced only by degradation (Figs. 5 and 6).

RNA silencing is guided by two major classes of small RNAs (sRNAs), termed miRNAs and siRNAs that are 20–25 nucleotides in length. sRNAs bear high sequence homology to their target loci, which confers specificity on the silencing process. Host RNAs are targeted by miRNA-mediated silencing and also by transitive (ta)siRNA-mediated silencing, while RNA viruses are thought to be targeted only by siRNA-mediated silencing.

The biogenesis and activity of miRNAs, tasiRNAs, and virus-derived siRNAs involve a number of conserved steps. *MIR* genes, which encode miRNAs, are transcribed and form a partially dsRNA structure. This is processed by ribonuclease III-like enzymes of the DICER-like (DCL) family into a 20–25 nt duplex. The duplex then binds to an RNA-induced silencing complex (RISC), which includes a ribonuclease H-like protein of the ARGONAUTE (AGO) family. Upon binding to the RISC one strand of the duplex, the 'passenger' strand, is degraded, leaving the single-stranded 'guide' strand, or mature miRNA. The miRNA directs the AGO protein to

cleave endogenous transcripts in a sequence-specific manner. In addition to degrading mRNAs by endonucleolytic cleavage, AGOs may in some cases inhibit their translation.

miRNAs may also direct cleavage of the transcripts of *TAS* genes, which encode tasiRNAs. Using the cleaved *TAS* transcripts as templates, dsRNA is generated by cellular RDR enzymes. These transcripts are processed into sRNA duplexes by the activity of DCL enzymes. The duplexes bind to a RISC and the passenger strand is degraded, leaving the single-stranded, mature tasiRNA. The mature tasiRNA directs the endonucleolytic cleavage activity of AGO against mRNAs containing complementary sequences.

Virus-derived siRNAs are generated by a mechanism related to that which generates miRNAs and tasiRNAs. RNAs of invading viruses are initially cleaved into sRNA duplexes by DCL enzymes. Cleavage may occur because of the formation of dsRNA during viral replication, recognition of aberrant features of viral RNA (e.g., secondary structural features), or abnormally high expression levels of the viral RNA. The virus-derived sRNA duplexes bind to a RISC, which degrades the passenger strand. Mature virus-derived siRNAs direct sequence-specific degradation of viral RNA by the RISC. There is also a systemic signaling phase of RNA silencing that is triggered by RNA viruses and which initiates silencing-based resistance against the virus in distant, uninfected parts of the plant. Although assumed to involve mobile RNA, the exact nature of this signaling is not resolved.

The importance of RNA silencing in antiviral defense is indicated by the fact that most, if not all, plant viruses have evolved proteins that inhibit RNA silencing to some extent. These viral silencing suppressors differ from each other in many respects including the point, or points, at which they exert their inhibitory activity on the RNA silencing pathways (Figs. 5 and 6). The 2b protein, the silencing suppressor protein encoded by cucumoviruses, inhibits antiviral silencing by binding ds sRNA molecules. It also binds to certain AGO proteins, which is important in disease symptom induction and in viral manipulation of host-insect (e.g., vector) interactions. Crystal structures have been obtained for two tombusviral p19 silencing suppressor proteins. P19 operates by binding 21 nt siRNAs in a size-selective manner, sequestering them and preventing their incorporation into a RISC. Many other viral silencing suppressors also appear to act, at least in part, through sequestration of sRNAs, for example the potyviral P1/HC-Pro or the carmoviral p21 protein, while the carmovirus p38 (which is also the viral coat protein) inhibits sRNA-mediated dicer action. Strikingly different approaches to the disruption of RNA silencing are demonstrated by the P0 silencing suppressor proteins of poleroviruses and the RNase III type silencing suppressors of criniviruses. P0 suppressors act as F-box proteins that promote ubiquitination and consequent proteasome-mediated destruction of AGO1 (Figs. 5 and 6). The RNase III type silencing suppressors degrade ds sRNAs.

RNA Silencing and Pathogenesis

The first indications that inhibition of RNA silencing pathways may cause symptom induction came from studies where viral silencing suppressor proteins were expressed constitutively in transgenic *A. thaliana*. These transgenes induced phenotypes that were reminiscent of, though not identical to, virus symptoms. It was found that these symptom-like phenotypes were caused by disruption of the miRNA-mediated silencing pathway, which is crucial in the regulation of plant development. As discussed previously, viral silencing suppressor proteins inhibit various steps in the silencing pathway (see 'Viral counter-defense: RNA silencing and its suppression by viruses'). In some cases disruption of miRNA-mediated silencing may perhaps be incidental, resulting from targeting of components of the miRNA pathway that are shared with the antiviral siRNA-mediated silencing pathway. However, in the case of the CMV 2b silencing suppressor protein its ability to interact with component(s) of the miRNA pathway and induce strong symptoms varies considerably between strains. This suggests that some silencing suppressors can selectively target the miRNA pathway. It remains to be seen what advantage or disadvantage this might have for the virus.

Role of B Cells and Antibodies in Controlling Bacterial Pathogens

Nicholas J Mantis, Wadsworth Center, New York State Department of Health, Albany, NY, United States

© 2019 Elsevier Inc. All rights reserved.

As the workhorses of our internal defense system, we owe an enormous debt to antibodies. Responding to external threats such as disease-causing microorganisms, protein antibody molecules are released by specialized immune cells into the blood stream to disarm the threat. Their mode of attack is target recognition: millions of different molecules can be created, each with a different binding site, which can identify distinctive proteins on their specifically assigned foe with pinpoint accuracy. From *Anatomy of a Killer*. [NobelPrize.org](https://www.nobelprize.org).

Perspective

Antibodies are the primary means by which the immune system eliminates bacterial pathogens from the human body. Antibodies clear bacteria that have gained access to circulation or normally sterile tissues, such as the liver and heart. Antibodies also protect the mucosal or “wet” surfaces of the human body, such as the lungs, oral cavity, urogenital tract, and the gastrointestinal tract, which are constantly exposed to a spectrum of opportunistic and pathogenic microorganisms.

When a host encounters a pathogen for the first time, there is an initial lag before the first wave of antibodies arrive on the scene. It is the job of the innate immune system to keep the invading bacteria at bay, while antibody-producing cells or “B cells” are enlisted and dispatched to the site of infection. The initial sortie consists of IgM antibodies. Although IgM antibodies are relatively low specificity and low affinity, they can resolve infections by working in concert with the innate immune system to lyse and engulf invading pathogens.

The second offensive, which appears 5–7 days after the start of an infection, is led by IgG or IgA antibodies, depending on the anatomical compartment. IgG antibodies predominate in the systemic compartment (e.g., blood, liver, spleen, heart), while IgA antibodies are the principal antibody type in mucosal secretions (e.g., saliva, intestinal mucus). The invading bacteria are soon confronted by swarms of IgG and IgA antibodies that fasten themselves to surfaces and appendages, such as flagella.

Antibody-coated bacteria have little chance of escape. In the systemic compartment, IgG-coated microorganisms are engulfed by professional phagocytic cells like neutrophils and macrophages. Or they are attacked by complement, a cascade of serum proteins that form pores in bacterial cell walls. In either case, IgG-coated pathogens are destroyed. In mucosal compartments, IgA-coated bacteria become entrapped in mucus and are unable to gain a foothold on host tissues. Consequently, IgA-bacteria immune complexes are eliminated from the body through normal physiologic processes such as peristalsis, mucociliary action, and coughing.

The job of B cells is not over when an acute infection is cleared. A subset of B cells known as plasma cells (effectively antibody “factories”) takes up residence in peripheral tissues and bone marrow and secretes pathogen-specific IgG or IgA for months or even years. These so-called long-lived plasma cells provide a continuous supply of pathogen-specific antibodies in blood and mucosal secretions, positioned to intercept a pathogen upon its return. The term “antibody titer” refers to the levels of a given pathogen-specific antibody in a particular body fluid.

Another subset of B cells, called memory cells, patrols central and peripheral tissues, on the look-out for return visitors. Memory B cells remain quiescent until they reencounter a pathogen-derived product known as an antigen. At this point, some of the memory B cells will differentiate into plasma cells to further increase levels of circulating antibody, while others will reenter lymph nodes and undergo additional rounds of antibody gene editing through a process known as somatic hypermutation (SHM), yielding new swarms of antibodies with greater affinities for their targets. Through repeated rounds of SHM, B cells give rise to a broad and essentially infinite diversity of antibodies capable of adapting to the ever-evolving onslaught of microbial invaders.

The goal of this article is to provide an introduction to how antibodies and B cells function in immunity to bacterial pathogens. Considering the sheer number of bacteria that cause disease in humans, it is not possible to address them all in a single article. Therefore, for the sake of illustration, the discussion will be limited to the nine bacterial pathogens (and their respective toxins, when appropriate) for which there are currently approved vaccines in the United States (Table 1). For a detailed description of these vaccines and their targets, the reader is referred to *The Pink Book*, published by the Centers for Disease Control and Prevention (CDC). All nine of the vaccines work by stimulating pathogen-specific antibodies that target exotoxins, promote complement-dependent killing, mediate opsonophagocytosis, and/or prevent colonization of mucosal epithelial surfaces.

Antibodies, B Cells, and the Nobel Prize

The discovery of the inner workings of antibodies and B cells has gone hand-in-hand with the pursuit of vaccines to combat some of the most significant killers in public health. In the early 20th century, diphtheria caused more than 200,000 cases and greater than 15,000 deaths per year in the United States alone. Today, almost a century after implementation of a universally administered vaccine, diphtheria is essentially eradicated in the United States. The etiological agent of diphtheria is the aerobic gram-positive

bacterium, *Corynebacterium diphtheriae*, which colonizes the human nasopharynx and secretes an extraordinarily potent and fast-acting toxin called diphtheria toxin. For physicians and scientists in the late 1800s, it was a mystery how an infection seemingly localized to the throat could be so deadly. Equally mysterious was how the immune system works to combat infectious agents like diphtheria.

It was Emil Adolph von Behring (1854–1917) and Kitasato Shibasaburo (1853–1931) who first identified a soluble substance in the blood of convalescent animals that when injected into naïve animals imparted protection against diphtheria. The protective substance, termed “antitoxin,” established the concept of passive immunity and revolutionized therapies for diphtheria at the turn of the 20th century. In 1901, the first Nobel Prize in Physiology or Medicine was awarded to Emil von Behring “for his work on serum therapy, especially its application against diphtheria, by which he has opened a new road in the domain of medical science and thereby placed in the hands of the physician a victorious weapon against illness and deaths.” Within a matter of years, public health laboratories, including the New York State Department of Health, were generating diphtheria antitoxin in horses and using it statewide in children to treat disease. An antitoxin therapy against tetanus toxin soon followed.

Of course, we now know that antibodies are responsible for the soluble “antitoxin” activity described by Emil von Behring and Kitasato Shibasaburo and characterized by other early immunologists, including Paul Ehrlich. These early discoveries are documented in the articles of “Microbe Hunters,” Paul de Kruif’s 1926 book that profiles the pioneers of immunology and microbiology.

A more thorough understanding of the biochemical nature of antibodies and the cells involved antibody production emerged in the early 20th century, as documented in a brief historical review of B cells by the preeminent immunologist, Dr. Max Cooper. Milestones in the field of antibodies were acknowledged by the Nobel Prize committee. For example, the 1919 Nobel Prize in Medicine or Physiology was awarded to the Belgian microbiologist Jules Bordet for the discovery of complement proteins that promote bacterial killing in conjunction with antibodies. The Australian born immunologist, Sir Frank Macfarlane Burnet, received the 1960 Nobel Prize in Physiology or Medicine for the clonal selection theory, which essentially argued that an antibody of a given specificity arises from a single B cell clone that expands in the presence of its cognate antigen (i.e., an antibody’s target). The discovery that antibodies arise as a result of self-imposed genetic engineering through processes known as VDJ recombination and SHM occurred in the 1970s. In 1972, Gerald M Edelman and Rodney R Porter shared the Nobel prize for the elucidation of the structure and function of antibody molecules at the protein level. A little more than a decade later, the 1984 Nobel Prize was awarded to Niels K Jerne, Georges J.F. Kohler, and César Milstein for the “...discovery of the principle for the production of monoclonal antibodies,” a technology that revolutionized the field of immunology and related disciplines and has given rise to modern drugs to treat breast cancer, leukemia, and other diseases. In 1987, Dr. Susumu Tonegawa was awarded a Nobel prize for elucidating how B cells are able to generate antibody diversity. Finally, the 2018 Nobel prize in Chemistry was awarded to the American microbiologist, George P. Smith, and the British immunologist, Sir Gregory P. Winter, for the ability to genetically manipulate antibodies in bacteria and bacteriophages, which has impacted biotechnology industry and fields of cancer therapy.

Antibody-Structure and Function

Today, antibodies are arguably some of the most well studied molecules in biology. In mice and humans, there are five isotypes: IgM, IgG, IgA, IgE, and IgD. Because IgE primarily functions in allergic responses and the role of IgD in immunity is still very much an active area of research, these two isotypes will not be discussed further. Rather, the focus of this article will be on IgM, IgG, and IgA. It should be underscored that the terms “immunoglobulins” and “antibodies” are frequently used interchangeably. However, there is an operational distinction: the term immunoglobulin refers to the bulk fraction of all antibodies precipitated from serum; the term antibody refers to a subset of immunoglobulins directed against a specific target or antigenic determinant (antigen).

Table 1 Role of antibodies in currently approved vaccines for bacterial pathogens.

Vaccine	Pathogen	Antibody mode(s) of action
Anthrax	<i>Bacillus anthracis</i>	Neutralize anthrax toxin
DT	<i>Corynebacterium diphtheriae</i>	Neutralize diphtheria toxin
Tetanus	<i>Clostridium tetani</i>	Neutralize tetanus toxin
aP	<i>Bordetella pertussis</i>	Neutralize pertussis toxin Inhibit bacterial adhesion to respiratory tract
Cholera	<i>Vibrio cholerae</i>	Inhibit bacterial colonization of intestine
Hib	<i>Haemophilus influenzae</i>	Complement-dependent SBA Opsonophagocytosis (OPA)
Meningococcus	<i>Neisseria meningitidis</i>	Complement-dependent SBA
Pneumococcus	<i>Streptococcus pneumoniae</i>	Opsonophagocytosis (OPA)
Typhoid	<i>Salmonella enterica</i> spp. Typhi	Opsonophagocytosis (OPA)

IgG Antibodies

IgG is often considered the prototypic antibody isotype. IgG consists of two identical polypeptides of $\sim 50,000$ MW, known as the heavy chains (H), and two identical polypeptides of $\sim 25,000$ MW known as the light chains (L). Each heavy chain is paired covalently to a light chain in a H-L configuration. The two H chains are covalently linked to each other via a disulfide bond so that a single IgG molecule consists of HL + HL pair. Structurally, the IgG molecule is typically compared to the letter "Y" with each of the antibody's arms extending upward to engage with its cognate antigen. In reality, however, the arms have a degree of freedom due to a hinge region, such that at any given time an antibody may resemble something between a "Y" and a "T." The upward facing arms are referred to as the Fab regions and constitute the antigen binding elements. The tail or stalk is known as the Fc region. If you imagine an IgG molecule bound to the surface of a bacterium, the Fab elements would be associated with the pathogen, while the Fc region would be projecting outward.

Although the Fc elements are not interacting with the pathogen per se, they are essential for pathogen killing. Specifically, Fc elements are recognized by two components of the innate immune system: the complement system and phagocytic cells like macrophages and polymorphonuclear cells (PMN). The complement system is a collection of more than two dozen serum proteins that work in concert to promote bacterial cell lysis through the formation of pores in bacterial cell walls. Phagocytic cells recognize and engulf antibody-coated bacteria through surface expressed Fc receptors (FcR). Fc receptors specific for IgG are referred to as Fc γ R. Thus, bacterial pathogens coated with IgG are either killed through complement-mediated lysis or cleared by phagocytic cells that express Fc-receptors.

IgG's two identical Fab elements involved in binding to antigens (e.g., flagella, lipopolysaccharide, toxins) and a single Fc domain that serves as a molecular adaptor recognized by complement and phagocytes, can be separated from each other by proteolytic digestion. Treatment of IgG with papain, a cysteine protease from the papaya plant, cleaves IgG at its hinge region and liberates the two monovalent Fab elements, which are referred to as Fab fragments, from the Fc element. Treatment of IgG with the acid protease, pepsin, also clips IgG at its hinge and releases the stalk, but in this case the two Fab elements remain joined to each in a molecular form known as F(ab) $_2$. Thus, Fab fragments are monovalent (i.e., one antigen binding site) molecules, while whole IgG molecules and F(ab) $_2$ fragments are bivalent (i.e., two antigen binding sites).

IgG-Antigen Interactions

The interaction of a given IgG antibody (Ab) with its antigenic determinant (Ag) is non-covalent and reversible. As such, the interaction is essentially a bimolecular reaction where $Ab + Ag \rightleftharpoons Ab-Ag$. The strength of an antibody's interaction with its antigen is driven by a net negative change in the Gibbs free energy, as a result of changes in enthalpy (heat) and entropy (structure). The rate of association (k_a) is expressed as $M^{-1} s^{-1}$ and the rate of dissociation (k_d) is expressed as s^{-1} . The equilibrium constant or K_D (M) is defined as $free [Ab] [Ag] / [Ab-Ag]$. K_D is the most commonly used reference point when citing an antibody's strength.

Strictly speaking, an antibody's affinity for its target is derived by measuring the binding kinetics of monovalent Fab fragments with its antigen using techniques like surface plasmon resonance (SPR). Fab binding affinities (K_D) range from weak (micromolar; 10^{-4} – 10^{-6}) to very strong (picomolar; 10^{-10} – 10^{-12}), with most falling within the nanomolar range (10^{-7} – 10^{-9}). In practice, however, avidity may be a more appropriate measure of an antibody's strength than affinity, since avidity takes into account the fact that IgG is bivalent and may be able to engage two antigens simultaneously, thereby affecting the overall stability of that antibody-antigen interaction. In simple terms, avidity is equivalent to a person holding onto a vertical pull-up bar with both hands. If one hand comes off the bar temporarily, the other hand is still holding tight. Together, however, two hands make for a more stable grasp of the bar than just one hand. Likewise, antibody avidity is a measure of the strength of an interaction when both Fab arms can engage their targets simultaneously, which occurs frequently with highly repetitive bacterial surface antigens like LPS and capsular polysaccharides (CPS).

IgM and IgA Antibodies

IgM and IgA antibodies share the basic architecture of IgG but differ in several important respects. The most significant difference is valency. IgM is secreted by B cells as a pentamer in which five IgM molecules are linked via their Fc tailpieces to form a rosette-like structure with 10 Fab elements facing outwards. This unique arrangement is consequential. IgM antibodies, which are the first to arrive on the scene of a new infection, tend to have low binding affinities for their targets. However, what IgM antibodies lack in affinity, they make up for in avidity. The 10 Fab elements enable IgM to hold tight to polymeric antigens like LPS, CPS and flagella. In addition, IgM's Fc region is an extremely potent activator of the complement system. These two properties (i.e., high-avidity binding and potent complement activation) enables IgM to keep bacterial invaders at bay until IgG reinforcements arrive on the scene.

IgA is the predominant antibody type in most mucosal compartments. In the gut, for example, IgA-producing B cells (plasma cells) outnumber IgG and IgM plasma cells by approximately 10 to 1. IgA is generally produced as a dimer in which two IgA monomers are joined via their Fc tailpieces by a small protein called J chain. IgA is therefore tetravalent. Unlike IgG and IgM, IgA cannot activate the complement system. Rather, IgA functions in mucosal secretions like saliva, intestinal fluids and breast milk where serum components like complement are absent.

Transport of IgM and IgA Into Mucosal Secretions

It is the polymeric nature of both IgA (dimer) and IgM (pentamer) that permits their transport into the secretions that bathe the alimentary tract, the upper respiratory tract, and the upper female genital tract. IgA and IgM are also actively transported by mammary epithelial cells into colostrum and breast milk. The process of antibody transport from inside to outside is most clearly exemplified in the gastrointestinal tract, where a single layer of rectangularly shaped epithelial cells are joined side-by-side to form a barrier that prevents the diffusion of macromolecules and particles (including viruses and bacteria) from the lumen ("outside") to lamina propria ("inside"). Dimeric IgA and pentameric IgM antibodies produced by B cells in the lamina propria are recognized by the so-called polymeric immunoglobulin receptor (pIgR) located on the underside (basolateral) of epithelial cells. The pIgR captures IgA and IgM and shuttles them intracellularly across epithelial cells, a process known as transcytosis. Once on the apical face (outside), the pIgR is proteolytically clipped and a fragment of the receptor, known as secretory component (SC), still bound to IgA or IgM, is released into the intestinal lumen. IgA and IgM complexed with SC are known as secretory IgA (SIgA) and secretory IgM (SIgM), respectively. SC is a large, heavily glycosylated protein that wraps around IgA and IgM's Fc elements, thereby protecting them from the harsh environment of mucosal secretions. The pIgR does not transport IgG, although there are other mechanisms by which small amounts of IgG can gain entry into mucosal secretions.

Evolution of Antibody Responses

As alluded to above, microbial pathogens that successfully breach the body's natural defenses and gain access to normally sterile environments like the blood or any of the visceral organs will soon come under attack by swarms of antibodies. The first wave consists of low-affinity, high-avidity IgM antibodies capable of triggering the complement system and bacterial lysis. The second wave consists of high-affinity IgG antibodies, which also recruit complement and phagocytic cells to sites of infection. If the infection originates in a mucosal compartment, then the second wave of antibodies consists mainly of IgA, rather than IgG. The generation of long-lived IgG or IgA secreting plasma cells in response to a particular infection guarantees a steady reserve of circulating antibodies should the microbial invaders return. As further reinforcements, memory B cells are poised to proliferate and produce new swarms of IgG and IgA antibodies on demand. But how do antibody responses originate in the first place and what drives the formation of plasma cells and memory cells? These are central concepts in immunology and well beyond the scope of this article. However, it is important to appreciate three basic tenets.

Tenet 1: Antibody Affinities Evolve With Time

The first tenet is that antibodies evolve during the course of an active infection from low- to high-affinity and tailor their specificity to available targets on the surface of the invading pathogen. B cells originate in the bone marrow and migrate into the periphery where they develop into so-called naïve mature B cells that express IgM (and IgD) on their surfaces. When naïve mature B cells "recognize" a foreign antigen they will secrete large amounts of IgM for immediate use in combatting an infection. Alternatively, they will enter the germinal centers and undergo switching to IgG- or IgA-positive B cells.

Broadly speaking, the conversion from IgM-positive to IgG-positive (or IgA-positive) B cells occurs in two stages. Class switch recombination (CSR) is a process where the DNA encoding the IgM Fc region is swapped for IgG or IgA Fc region. The choice between IgG and IgA Fc elements is dictated by the local environment. SHM is the process whereby the DNA encoding the antibody variable regions (V_H and V_L) are edited to generate a better "fit" with its antigenic determinant. This process is also referred to as affinity maturation, since the antibody's affinity for its target can increase by orders of magnitude as a result of SHM. Affinity maturation requires help from a number of other immune cell types, most notably follicular dendritic cells and T cells.

Tenet 2: Evolution is Driven SHM and Clonal Selection

The second tenet is that the process of SHM gives rise to an infinite number of antibodies against virtually any microbial protein or carbohydrate target. As defined earlier above, SHM is a process in which the DNA encoding an antibody's variable regions (V_H and V_L) are edited in an effort to improve overall binding affinity to its target. To be clear, any given B cell will produce antibodies of only one specificity (i.e., B cell "x" produces antibody "x," while B cell "y" produces antibody "y"). Therefore, the collective diversity of the antibody response to a given pathogen is dictated by the ensuing number of B cells that arise following infection. The term B cell "repertoire" refers to the total diversity of B cell specificities. However, B cell clones can give rise to progeny that carry minor variations in their variable regions that alter target specificity. B cell clone "x" can give rise to subclones x.1, x.2, x.3. which bind the same or nearly the same epitope but with slightly different affinities. The constant release of new generations of antibodies capable of saturating a given target has given rise to the concept of an antibody "swarm."

Tenet 3: B Cell Memory Guarantees Long-Term Immunity

The third tenet is that upon re-exposure to a pathogen, the recall antibody response is faster, more specific, and of higher magnitude than the first exposure, due to the existence of memory B cells. The preeminent immunologist Antonio Lanzavecchia

refers to memory B cells as the "...repository of an immune experience of an individual." In other words, memory B cells are the equivalent of an antibody hard drive that can be accessed on demand upon re-encounter with a pathogen. Concurrent with the formation of memory B cells are long-lived IgG or IgA plasma cells that can sustain circulating antibody levels over a period of years or even decades. In fact, modern day vaccines are predicated on the ability of a surrogate antigen or attenuated pathogen to elicit a memory B cell response capable of responding to an actual infection over a period of years or even decades.

In summary, a bacterial infection in a mucosal (e.g., lung, gut) or systemic (e.g., liver, kidney) compartment will elicit a two-phased antibody response (IgM followed by IgG and/or IgA) that will continue to mature or evolve until the pathogen is cleared. Long lived plasma cells will maintain circulating antibody titers for years to ward off a recurrent infection, while memory B cells will lie in waiting until called into action.

Antibody Function: Finding a Pathogen's Achilles' Heel

Just as the proverbial well-placed arrow to Achilles' heel led to the death of the mythic Greek warrior, antibodies eliminate bacterial pathogens by targeting sites of microbial vulnerability. To fully appreciate the shrewd nature of the immune system, it is important to recall the strategies used by pathogens to cause disease: exotoxins, evasion of innate defenses, tissue colonization, cellular invasion, and proliferation in the blood stream. B cells respond in kind to each of these insults by releasing their equivalent of poison arrows.

Bacterial Toxins, Virulence Factors, and Surface Polysaccharides as Antibody Targets

Without question, exotoxins are the most potent virulence factors associated with bacterial pathogens. Two prime examples are diphtheria toxin produced by *C. diphtheriae* and cholera toxin secreted by *V. cholerae* (Table 1). Diphtheria toxin is released by *C. diphtheriae* after the bacterium has colonized the human upper respiratory tract, while cholera toxin is produced when *V. cholerae* has set up shop in the small intestine. Diphtheria toxin kills mammalian cells by inhibition of protein synthesis as a result of ADP-ribosylation of elongation factor 2 (EF-2). Cholera toxin causes severe watery diarrhea by perturbing cyclic AMP levels in intestinal epithelial cells as a consequence of ADP-ribosylation of small G proteins. Strains lacking these toxins are essentially avirulent, attesting to the singular contributions of cholera and diphtheria toxins to disease. Three other pathogens listed in Table 1 produce exotoxins; *B. anthracis* (anthrax toxin), *C. tetani* (tetanus toxin) and *B. pertussis* (pertussis toxin).

Bacterial pathogens also express an array of other virulence factors involved in attachment to and invasion of mammalian hosts. Surface appendages like fimbriae and pili enable bacterial adherence to specific cell types. For example, both *B. pertussis* and *V. cholerae* express adhesins required for colonization of human epithelial cells. Other pathogens express macromolecular "syringes" or secretion systems on their surfaces that inject "effector" proteins into mammalian cells that facilitate bacterial entry into intracellular compartments. In fact, *Salmonella* species, including *S. enterica* serovar Typhi, employs two different so-called type-three secretion systems (T3SS) during infection of the gastrointestinal tract.

LPS, capsular polysaccharides (CPS), and exopolysaccharides (EPS) are classified as virulence factors by virtue of their ability to serve as shields against components of the innate immune system. The importance of CPS in pathogenesis is best exemplified by *H. influenzae*, a leading cause of bacterial meningitis in young children (Table 1). *H. influenzae* is a small, nonmotile Gram-negative bacterium that adheres to epithelial cells and mucins in the human upper respiratory tract. In some individuals, the bacterium becomes invasive and breaches epithelial defenses and surmounts the innate immune system to gain access to the blood stream. The invasive phenotype and ability to evade phagocytosis is associated with a specific CPS consisting of polyribosyl-ribitol-phosphate (PRP). Strains of *H. influenzae* that lack this specific CPS are associated with invasive disease much less frequently. Three other pathogens listed in Table 1 rely on capsule production to evade innate immunity and replicate within the human host: *S. pneumoniae*, *N. meningitidis*, and *S. Typhi*.

As a rule, immune responses to microbial pathogens, such as those listed in Table 1, are complex and involve antibodies targeting multiple different bacterial-associated antigens. However, when a single virulence factor like a toxin is central to disease manifestation, the most important antibody response may be against a single target. The list below demonstrates the strategies used by antibodies to exclude and/or clear bacterial pathogens from systemic and mucosal compartments.

Direct Neutralization of Toxins and Other Virulence Factors

The current anthrax, diphtheria, pertussis, and tetanus vaccines listed in Table 1 are designed specifically to elicit anti-toxin antibody responses. The primary mode by which antibodies neutralize toxins is by blocking attachment to host cell receptors. Antibodies that recognize epitopes on the binding subunits of anthrax, diphtheria, pertussis, and tetanus toxins have been described. However, toxin-neutralizing antibodies do more than just interfere with receptor binding events. In the case of anthrax, there are antibodies that prevent toxin oligomerization, pore formation, proteolytic cleavage, and subunit assembly. In fact, Raxibacumab is an FDA approved human IgG monoclonal antibody against anthrax toxin protective antigen (PA) designed as a pre-exposure prophylaxis in the event of anthrax being used in bioterrorism. Raxibacumab doesn't interfere with PA from binding to receptors on target cells, but it does prevent PA from associating with its toxic components, lethal factor and edema factor. Thus, antibodies are capable of interfering with essentially all the steps in the intoxication process.

Antibodies can also “neutralize” virulence factors associated with bacterial attachment and invasion of mammalian cells, as best exemplified by the acellular pertussis (aP) vaccine (Table 1). Whooping cough is caused by the Gram-negative bacterium, *Bordetella pertussis*, which colonizes the human upper respiratory tract where it secretes pertussis toxin. The aP vaccine consists of a collection of recombinant proteins that stimulates antibodies against pertussis toxin, plus several of the fimbriae and adhesins involved in bacterial attachment to the respiratory epithelium. Thus, antibodies against fimbriae and adhesins interfere with bacterial attachment to mucosal surfaces of the airway, while anti-toxin antibodies neutralize pertussis toxin that gains access tissues and circulation.

Activation of the Classical Complement Pathway

Simply stated, the complement system is a collection of more than two dozen serum proteins that function as a bridge between the innate and adaptive immune systems. The so-called classical complement pathway is initiated when two or more IgM or IgG antibodies are deposited in close proximity to each other on the surface of a pathogen. Clusters of IgM or IgG are recognized by the complement component, C1. C1 has an affinity for the Fc elements of IgM and IgG (namely IgG1, IgG2, and IgG3 subclasses), but not IgA. IgM, by virtue of its pentameric star-like structure, is particularly effective at recruiting C1. Once bound, C1 recruits a cascade of additional complement proteins to the bacterial cell surface, resulting in the assembly of the membrane attack complex (MAC). The MAC is a molecular channel or pore in the bacterial cell wall that perturbs cellular osmolarity and results in cell death by lysis.

Antibody-dependent, complement-mediated killing is a significant biological activity associated with the *H. influenzae* and *N. meningitidis* vaccines (Table 1). The *H. influenzae* vaccine consists of the type B capsular polysaccharide (PRP) chemically linked to a carrier protein like the non-toxic variant of diphtheria toxin CRM 197 or inactivated tetanus toxin. The *N. meningitidis* vaccines in the United States consist of polysaccharide protein conjugates and various combinations of recombinant protein surface antigens. In all cases, vaccination stimulates serum IgG of antibodies capable of decorating (opsonizing) the surfaces of *H. influenzae* and *N. meningitidis* and subsequently activating complement-mediated killing. In fact, efficacy of *N. meningitidis* vaccines correlates with how well antibodies from a vaccinated individual perform in a standardized serum bactericidal assay (SBA) (McIntosh et al., 2015).

Killing by Opsonophagocytosis

Opsonophagocytosis is the engulfment, by macrophages and other phagocytic cells like neutrophils, of bacteria opsonized with antibodies and/or complement proteins. Thus, microbial cells in the blood or within a specific tissue that become coated with IgG are soon recognized by patrolling macrophages and neutrophils. Recognition occurs through specific surface-expressed FcγRs on the phagocytes. When multiple FcγRs are engaged simultaneously, it cues the phagocyte to envelope its prey and confine it within an intracellular compartment known as the phagosome. The phagosome is a dead-end for most microbial pathogens. Within minutes, the encased bacteria are exposed to reactive oxygen species, acidic pH and a barrage of degradative enzymes.

Opsonophagocytosis is a primary means by which antibodies promote the clearance of *S. pneumoniae* and accounts for the biological activity associated with the successful pneumococcal vaccines in widespread use around the globe (Table 1). In fact, one measure of vaccine efficacy is the opsonophagocytosis killing (OPK) assay, which involves the engulfment of *S. pneumoniae* by human neutrophils in the presence of serum from a vaccinated individual. Antibodies also coordinate opsonophagocytosis in the clearance of *H. influenzae* and *S. Typhi*.

Secretory IgA Paralyze and Entrap Bacteria in Mucosal Secretions

In mucosal compartments, secretory IgA (SIgA) plays by different rules. As noted earlier in the article, IgA is actively transported by the pIgR into intestinal secretions in the form of SIgA. SIgA does not activate complement, nor does it promote opsonophagocytosis. Instead, SIgA functions by a process known as immune exclusion in which pathogens are aggregated by antibodies and entrapped in mucus. Immune complexes between SIgA and microbial invaders are not only restricted in their ability to diffuse through mucus but can also be cleared from the body through normal physiologic processes such as cilia movement in the respiratory tract and peristalsis in the intestinal tract.

The concept of immune exclusion is best exemplified in the gut where pathogenic bacteria like *V. cholerae* set up shop and cause the disease cholera (Table 1). The bacteria employ flagellar-based motility to penetrate intestinal mucus and then deploy pili to secure themselves onto epithelial cells. Local production of cholera toxin results in a deadly bout of watery diarrhea that can kill an otherwise healthy adult within a matter of hours. Thus, the battle between host (antibodies) and microbe occurs in the intestinal lumen. As it turns out, antibodies against LPS are associated with immunity to *V. cholerae* infection, presumably because they are able to entrap the bacteria in mucus well before *V. cholerae* can gain a foothold on the epithelium. In contrast, anti-cholera toxin antibodies fail to protect against disease because the toxin is released only when the bacterium is in intimate contact with host epithelial cells, where there is little time or space for antibodies to intercept their target.

Anti-LPS SIgA likely functions by more than one mechanism. On the one hand, they are highly effective at promoting bacterial agglutination to the point where “rafts” of bacteria are so large that they are visible to the naked eye when the assay is performed in a

test tube. Experimentally, agglutination has also been observed in the intestinal lumen, so there is credence for immune exclusion play a role in vivo. On the other hand, recent evidence has demonstrated that anti-LPS IgA antibodies are potent inhibitors of *V. cholerae* motility. In fact, certain IgA preparations have been shown to completely paralyze *V. cholerae* within just a matter of minutes. This has led to the hypothesis that SIgA might work at two levels: paralyze, then handcuff. The whole cell-killed and live attenuated cholera vaccines in current use are administered to children and adults by the oral route as a means to stimulate *V. cholerae*-specific SIgA in the intestinal tract.

Additional Modes of Antibody Function

There are certainly under-explored or yet to be discovered mechanisms by which antibodies function in clearing bacterial pathogens, beyond complement activation, opsonophagocytosis, and immune exclusion (Lu et al., 2018). For example, there are reports describing monoclonal IgM and IgG antibodies against outer surface proteins of *Borrelia hermsii* (relapsing fever) and *B. burgdorferi* (Lyme disease) that cause direct bacterial lysis, independent of complement. There are also examples of antibodies that playing a central role in immunity against obligate intracellular pathogens like *Ehrlichia chaffeensis*, the causative agent of tick-borne disease ehrlichiosis. The recent discovery of an intracellular Fc receptor known as TRIM-21 has already challenged the conventional notions about antibody function. Finally, in the past several years has it become apparent that subtle differences in Fc glycosylation patterns on human IgG can have profound effects on antibody functionality.

Back to the Future With Monoclonal Antibodies (MAbs)

With the global crisis in antibiotic resistance, there is a desperate need to find alternative measures to control bacterial pathogens. As we look forward, new generations of vaccines are an obvious avenue to pursue. But an equally exciting prospect is the use of recombinant monoclonal antibodies (MAbs) in prophylactic and therapeutic applications. Historically, MAbs have been generated from mice; B cells from immunized animals are immortalized by hybridoma technology and then isolated as individual clones that secrete antibodies of a single specificity. Hence, the term “monoclonal antibody.” In the past decade, however, it has become technologically feasible to generate MAbs from humans, using recombinant antibody technology as described by Corti and Lanzavecchia (2014). Basically, the genes encoding the variable regions of antibodies of interest are cloned and expressed in mammalian cell lines. In the case of HIV, Ebola and other viruses, recombinant antibodies have been shown to afford short term immunity. It is not inconceivable that MAbs will be used as a supplement or even as a replacement for antibiotics for some hard to treat bacterial infections. In a back to the future-like scenario, the use of high tech, recombinant “antitoxins” may soon be routine in the clinic.

Glossary

Apicomplexans Parasitic protists belonging to the supergroup Alveolata, many of which possess a remnant, nonphotosynthetic plastid of secondary endosymbiotic origin.

Apicoplast Remnant secondary plastid of apicomplexans.

Chlorarachniophytes Marine amoeboflagellate algae with plastids of green algal origin. Together with cryptophytes, noteworthy for their possession of a nucleomorph.

Chloroplast Photosynthetic chlorophyll-containing eukaryotic organelle of endosymbiotic origin, sometimes used to specifically refer to the photosynthetic organelle of green algae and their land plant descendants.

Chromerids Marine unicellular algae with chlorophyll *a*-pigmented plastids of secondary endosymbiotic origin. Related to apicomplexans and dinoflagellates.

Cryptophytes (cryptomonads) Marine and freshwater unicellular algal lineage; most possess a secondary plastid of red algal ancestry. Together with chlorarachniophyte algae, noteworthy in that they possess a nucleomorph.

Dinoflagellates Ecologically significant lineage of microbial eukaryotes, comprising photosynthetic and nonphotosynthetic species. Diverse in the pigmentation and evolutionary origin of their plastids.

Endosymbiosis The process by which a free-living cell (prokaryotic or eukaryotic) becomes a permanent resident inside another cell.

Euglenids Abundant and well-studied algal lineage with a plastid of green algal origin (chlorophyll *a* and *b* pigments).

Glaucophytes (glaucocystophytes) Freshwater algal lineage containing a chlorophyll *a*-pigmented plastid of primary endosymbiotic origin. Unlike other plastids, glaucophyte plastids possess a carboxysome and a layer of peptidoglycan between the inner and outer plastid membranes, presumably inherited from their cyanobacterial progenitors.

Green algae Algal lineage from which land plants evolved. Plastids contain chlorophylls *a* and *b*.

Haptophytes Abundant and ecologically significant marine and freshwater algae, many of which possess a haptonema (a flagellum-like structure) and scales made of calcium carbonate called coccoliths.

Nucleomorph Remnant nucleus of secondary endosymbiotic origin, found in cryptophyte and chlorarachniophyte algae between the inner and outer pairs of plastid membranes.

Plastid Organelle of cyanobacterial ancestry residing within plant and algal cells. The term encompasses both photosynthetic and nonphotosynthetic forms.

Primary endosymbiosis The engulfment and retention of a photosynthetic prokaryote by a heterotrophic eukaryote. Gives rise to a primary plastid.

Red algae (rhodophytes) Unicellular and multicellular group of algae with chlorophyll *a*-containing plastids surrounded by two membranes.

Secondary endosymbiosis Acquisition of a primary plastid-containing alga by a nonphotosynthetic eukaryote. Gives rise to a secondary plastid surrounded by three or more membranes.

Stramenopiles (heterokonts) Diverse assemblage of photosynthetic and nonphotosynthetic unicellular and multicellular eukaryotes. Photosynthetic members possess chlorophyll *a*+*c*-containing plastids.

[☆]*Change History:* August 2016. C.J. Grisdale and J.M. Archibald added the Sections "Tertiary Endosymbiosis" and "Integration and Gene Transfer in Tertiary Endosymbiosis," updated the text in all sections, Table 1 and added references to "Further Reading."

ER	Endoplasmic reticulum
EST	Expressed sequence tag
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
TIC	Translocons of the inner chloroplast membrane
TOC	Translocons of the outer chloroplast membrane

Defining Statement

Secondary endosymbiosis is the uptake and retention of a eukaryotic alga by a nonphotosynthetic host, a process that has given rise to a significant fraction of algal biodiversity. This article summarizes current knowledge of the pattern and process of secondary endosymbiosis from the perspective of cell biology, genetics, and evolution. Higher-order “tertiary” endosymbioses are also considered.

The Origin of Eukaryotic Photosynthesis**Primary Endosymbiosis**

Endosymbiosis has had a profound impact on the evolution and diversification of eukaryotes. Mitochondria and plastids, the energy-generating organelles of modern-day eukaryotes, evolved from free-living prokaryotes that were taken up by eukaryotic hosts and transformed into permanent subcellular compartments. In extant cells, these organelles now function as the sites of respiration and oxygenic photosynthesis, respectively. Unlike the endosymbiotic origin of mitochondria, which appears to have occurred in the common ancestor of all known eukaryotes, the endosymbiosis that gave rise to plastids occurred after the deepest divergences in eukaryotic evolution had taken place. This pivotal event paved the way for the evolution of a diverse array of algal lineages and for the spread of plastids between unrelated groups of eukaryotes by “secondary” (ie, eukaryote–eukaryote) endosymbiosis.

Photosynthesis is widespread in bacteria, but oxygenic photosynthesis occurs only in the cyanobacteria, a lineage of unicellular and colony-forming prokaryotes once referred to as blue-green algae. Among bacteria, only cyanobacteria possess both photosystems I and II. This allows them to use light energy to split water and produce ATP, NADPH, and glucose, liberating oxygen in the process. These products, together with carbon dioxide, are then converted to carbohydrate via the Calvin cycle. The fundamental similarities of cyanobacterial photosynthesis and that of plastids, which also possess photosystems I and II, argue strongly that eukaryotes derived their plastids from a harnessed cyanobacterium, in what is generally referred to as a “primary” endosymbiotic event (Fig. 1(a)).

The evidence supporting a cyanobacterial ancestry for plastids is overwhelmingly strong and is based on a large amount of biochemical, ultrastructural, and molecular phylogenetic data. As discussed below, three eukaryotic lineages – the green algae (and land plants), red algae, and glaucophyte algae – possess primary plastids (Table 1), indicating that they arose directly from this landmark event.

One of the hallmark features of plastids is their membranes. Many bacteria have two membranes, with a layer of peptidoglycan in between. Based on what is understood about the process of phagocytosis in eukaryotes, one would expect plastids to be surrounded by three membranes, two from the cyanobacterial endosymbiont and a third, outermost membrane derived from the phagosomal membrane of the heterotrophic eukaryote (Fig. 1(a)). However, primary plastids possess only two membranes, both of which appear to be cyanobacterial in origin (the plastids of glaucophyte algae also possess a peptidoglycan layer (Fig. 1(b))). One possible explanation is that the engulfed cyanobacterium “escaped” the confines of the host cell phagocytic vacuole and took up residence in its cytoplasm. Regardless, it is reasonable to assume that the photosynthetic abilities of the endosymbiont were of great benefit to the eukaryotic host and provided a strong selective advantage to those cells that happened to retain their endosymbionts for progressively longer periods of time. The two cells became increasingly dependent on one another and, eventually, the cyanobacterial endosymbiont evolved into a fully integrated component of the host.

Endosymbiotic gene transfer and plastid protein import

While the genomes of modern-day cyanobacteria range from ~2 to 12 Mbp in size and encode >1000 genes, the largest and most gene-rich plastid genomes are only ~0.5 Mbp (eg, the green alga *Floydella*) and possess at most ~250 genes (eg, the red alga *Porphyra*). Roughly half of this massive genome reduction involved the elimination of genes no longer essential for intracellular life. The remainder involved the transfer of genes from the endosymbiont to the host nuclear genome, a process known as endosymbiotic gene transfer (Fig. 1(a)). Based on the similarities in gene content of plastid genomes of red, green, and glaucophyte algae, much of the plastid-to-nucleus gene transfer probably occurred early in the evolution of photosynthetic eukaryotes, in a common ancestor shared by all primary plastid-containing algae. However, this has been an ongoing process throughout the evolution of photosynthetic eukaryotes and probably still occurs in at least some lineages. Indeed, examination of plant nuclear genomes reveals

Fig. 1 Plastid evolution by primary and secondary endosymbiosis. (a) Diagram depicting the process of primary endosymbiosis in which a nonphotosynthetic eukaryote engulfs a cyanobacterium. The process involves extensive loss of DNA from the cyanobacterial genome as well as transfer of cyanobacterial genes to the nuclear genome of the host eukaryote. (b) Primary plastid-containing cell with two membranes surrounding its plastid, both of which are cyanobacterial in nature. The plastids of glaucophyte algae retain a layer of peptidoglycan between the two membranes. (c) Diagram shows the process of secondary endosymbiosis, whereby a primary plastid-containing alga is taken up by a heterotrophic eukaryote. Secondary endosymbiosis involves the large-scale movement of cyanobacterial and eukaryotic DNA from the primary host nucleus (N1) to the secondary host nucleus (N2), as well as DNA loss. DNA transfers from the plastid to the primary nucleus or directly to the secondary host nucleus are also possible. (d) Secondary plastid-containing eukaryote with three or four membranes surrounding the plastid (the primary host plasma membrane is believed to have been lost in euglenids and some dinoflagellates). The space between the inner and outer pairs of membranes corresponds to the remnant cytosol of the primary plastid-containing alga and, in cryptophytes and chlorarachniophytes, still harbors the primary host nucleus. The outermost plastid membrane in cryptophytes, haptophytes, and stramenopiles is contiguous with the nuclear envelope and endoplasmic reticulum (ER). Movement of DNA involving the mitochondrion has been omitted for simplicity. Abbreviations: CB, cyanobacterium; IM, inner membrane; M, mitochondrion; N, nucleus; OM, outer membrane; PL, plastid.

that they are littered with numerous and often large (albeit presumably nonfunctional) fragments of plastid DNA. Experimental evidence has shown that endosymbiotic gene transfer (EGT) of plastid genes in *Tobacco* plants is possible via direct DNA transfer, resulting in functional expression of the gene in the nuclear genome.

An early requirement for the functional transfer of endosymbiotic genes to the host nucleus was the establishment of a protein-targeting apparatus capable of directing the products of these nuclear-encoded genes back to their organelle of origin. Genomic and proteomic analyses of primary plastid-containing organisms have revealed that ~1000 proteins function in the chloroplast. Most of these are now nucleus-encoded and targeted to the organelle posttranslationally. This targeting is accomplished by an N-terminal "transit peptide" extension of ~20–150 amino acids present on nearly all plastid-targeted proteins. These extensions are poorly conserved at the primary sequence level but possess a net positive charge and a hydrophobic N-terminus.

Transit peptides are recognized by receptors in the plastid membrane and the preprotein is then pulled into the plastid by a pair of translocation machineries. These are referred to as TIC and TOC, for translocons of the inner and outer chloroplast membranes, respectively. Once inside the plastid, the transit peptide is cleaved from the preprotein to yield the mature protein product. Genomic comparisons have revealed that the plastid import machineries of red and green algae are predominantly cyanobacterial in nature and quite similar to one another, suggesting that they were established in their common ancestor (less is known about protein

Table 1 Distribution of primary and secondary plastids and their basic characteristics

Organism	Putative origin	Cellular location	Membranes	Pigmentation
Glaucophytes	1°	Cytosol	2 ^a	Chl <i>a</i> phycobiliproteins

Abbreviations: Chl, chlorophyll; RER, rough endoplasmic reticulum.

^aGlaucophyte plastids possess a layer of peptidoglycan between the inner and outer membranes.

^bThe cryptophytes and chlorarachniophytes are unusual in that the nucleus of their red and green algal endosymbionts persists in highly degenerate form called a nucleomorph. In both lineages, the nucleomorph is located in the space between the inner and outer pairs of plastid membranes, which is derived from the remnant cytosol of the primary algal host cell and sometimes referred to as the periplastid space.

^cIn cryptophytes, haptophytes and most stramenopiles (heterokonts), the outermost plastid membrane is continuous with the endomembrane system of the host cell. The plastid thus physically resides within the lumen of the rough endoplasmic reticulum, an arrangement sometimes referred to as the chloroplast endoplasmic reticulum.

^dDinoflagellates are exceptionally diverse in terms of the type of plastid they possess. Among photosynthetic dinoflagellates, the chlorophyll *a+c* and peridinin-pigmented plastid is most common. Plastid membrane number varies depending on plastid type (see main text).

^eThe plastids in these lineages are not physically connected to the host cell endoplasmic reticulum, although they are surrounded by additional membranes and thus enveloped by a region of endomembrane lumen of unknown origin.

^fThe general consensus is that 4 membranes surround the apicomplexan plastid, though some studies suggest that this number can vary.

^g*Chromera velia* and *Vitrella brassicaformis* are newly discovered photosynthetic organisms with 4-membrane plastids whose genes most closely ally them with apicomplexans and peridinin plastid-containing dinoflagellates.

targeting to the plastids of glaucophytes, though it appears to be similar). While the TIC–TOC-based import pathway appears to be the predominant system for plastid protein import, it should be noted that protein targeting in the absence of canonical N-terminal signals is also possible. Exactly how this occurs is at present unclear.

While the nuclear genomes of plants and algae harbor hundreds or even thousands of genes encoding proteins that service the plastid, a significant fraction of the cyanobacteria-derived genes residing in the nuclear genomes of modern-day photosynthetic eukaryotes appear to have nothing to do with photosynthesis. For example, the plastid proteome of *Arabidopsis* has approximately 1500 curated proteins, while it is estimated that 4300–4500 nuclear genes may have been acquired from the ancestor of the plastid. Approximately 3000 nuclear genes have predicted chloroplast targeting signals, while a significant proportion (10–15%) of known plastid proteins lack identifiable targeting signals. The exact numbers are still being debated and analyses of other primary plastid-containing eukaryotes, such as the green alga *Chlamydomonas reinhardtii*, the red alga *Cyanidioschyzon merolae*, and the glaucophyte *Cyanophora paradoxa*, have yielded slightly lower estimates. Nevertheless, the cyanobacterial progenitor of the plastid clearly had a major impact on the nuclear genome of the ancestral eukaryotic phototroph, donating hundreds of genes whose products took on roles in a wide range of cellular processes unrelated to photosynthesis.

Secondary Endosymbiosis

Canonical plastids appear to have evolved only once in the history of life. That is, all plastids appear to trace to a single endosymbiotic event. However, primary plastid-containing organisms account for only a fraction of the known diversity of photosynthetic eukaryotes. A wealth of data clearly indicates that on multiple occasions plastids have spread from one eukaryote to another by a process known as “secondary endosymbiosis.” These events gave rise to a diverse set of environmentally, economically, and medically significant algal lineages. Secondary endosymbiosis (Fig. 1(c)) occurs when a primary plastid-containing alga is taken up by a nonphotosynthetic eukaryote and transformed into a “secondary” or “complex” plastid (Fig. 1(d)).

The process of secondary endosymbiosis is complicated by the fact that the bulk of plastid-targeted proteins are encoded in the primary host nuclear genome. Thus secondary endosymbiosis is not just the acquisition of a plastid by a new host. In order for a secondary plastid to be stably maintained and inherited, hundreds of nuclear genes must be transferred from the primary host nucleus to the secondary host nucleus. Comparative genomic analyses have shed light on the genetic processes that accompany this transformation. One of the most important advances has been the discovery that the nucleus of the algal endosymbiont still exists in some secondary plastid-bearing lineages (albeit in a miniaturized form). Among other things, this proves beyond all doubt that secondary endosymbiosis of plastids has occurred on multiple occasions.

Diversity of secondary plastid-containing algae

At the most fundamental level, secondary plastids are of two basic types: those derived from green algal endosymbionts and those that evolved from red algae. Two evolutionarily distinct lineages, the euglenids and chlorarachniophytes, possess “green” secondary plastids (Table 1). The euglenids are a relatively well-studied group of marine and freshwater algae, which include the laboratory specimen *Euglena*. In contrast, the chlorarachniophytes are a rare and poorly understood group of amoeboid flagellate algae that together with the cryptophytes are unique in that they still possess the nucleus of their algal endosymbiont, referred to as a “nucleomorph.” Four membranes surround the chlorarachniophyte plastid, whereas the euglenid plastid has three membranes (Table 1).

The evidence supporting a green algal ancestry for the plastids of both chlorarachniophytes and euglenids comes primarily from their shared possession of chlorophyll *b* (as do green algae and land plants) and from molecular phylogenies inferred from plastid-encoded genes. In the case of chlorarachniophytes, this has also been confirmed by analysis of nucleomorph genes. While the euglenid and chlorarachniophyte plastids are clearly of green algal origin, molecular phylogenies have thus far not revealed the closest free-living relatives of their endosymbionts within the green algal/land plant radiation.

A much larger number of eukaryotic algae harbor plastids believed to be of red algal origin. Perhaps best known are the stramenopiles (or heterokonts), which include unicellular forms such as diatoms and multicellular groups such as the giant kelps. Stramenopile plastids are surrounded by four membranes and contain chlorophyll *a+c* and the accessory pigment fucoxanthin (Table 1). The haptophytes are another well-known and ecologically significant algal lineage with “red” secondary plastids. Other groups include the cryptophytes, a relatively abundant group of marine and freshwater algae that possess a nucleomorph.

Red algae-derived plastids are also found in alveolates such as the dinoflagellates, notorious bloom formers that are also well known for their ability to “steal” the plastids of other secondary plastid-containing algae by tertiary endosymbiosis (see below), as well as the apicomplexans, a secondarily nonphotosynthetic group of parasites that include the malarial parasite *Plasmodium*. The most recently discovered red secondary plastid-containing lineage is Chromerida, containing the species *Chromera velia* and *Vitrella brassicaformis*. Recent genomic analysis of these species provides support for the hypothesis that chromerids are specifically related to apicomplexans and dinoflagellates. Chromerids are unicellular phototrophs with four-membrane, chlorophyll *a*-containing plastids (Table 1). As will be discussed below, the evolutionary history of red secondary plastids is complex and controversial. There are currently many unanswered questions regarding when these plastids were acquired and how they are related to one another.

Gene transfer and protein import in secondary plastids

As is the case for primary endosymbiosis, endosymbiotic gene transfer and gene loss play an important role in the establishment of secondary plastids. The plastid genomes of a variety of secondary plastid-containing algae have been sequenced and, as expected, their coding capacity is similar to that of the red or green algal plastids from which they evolved. This suggests that at the time of engulfment, most of the cyanobacteria-derived genes were already located in the nuclear genome of the primary alga. In secondary endosymbiosis, these genes must again be transferred en masse, this time from the primary host nucleus to that of the secondary host (Fig. 1(c)). Genes can also be transferred directly from the plastid to the secondary host nuclear genome.

In most secondary plastid-containing algae the process of gene transfer has gone to completion and the endosymbiont nucleus has disappeared. Even in cryptophytes and chlorarachniophytes, where a nucleomorph persists, its coding capacity is extremely limited, indicating that most of the genes present in the primary algal nucleus have relocated to the secondary host nucleus. A unique aspect of secondary endosymbiosis is the potential for transfer of eukaryotic genes from the primary algal nucleus to the secondary host nucleus. The functions of many of these genes presumably overlap with those already present in the nuclear genome of the secondary host, and they would be prone to degradation and loss. However, they also have the potential to acquire novel functions in their new genomic and cellular context or to replace their secondary host nuclear counterparts. The frequency and significance of “eukaryote–eukaryote” endosymbiotic gene transfer is currently poorly understood.

Unlike primary plastids, which are surrounded by two membranes, most secondary plastids are characterized by the presence of three or four membranes (Table 1), the outermost of which is thought to be derived from the phagosomal membrane of the secondary host (Fig. 1(c) and (d)). This fact has important ramifications for the process of protein targeting. Thus, a critical stage in the evolution of a secondary plastid is the establishment of a second import pathway – in addition to the transit peptide-based system already used by the engulfed algal cell – capable of targeting the products of plastid-derived genes now encoded in the new host nuclear genome to their compartment of origin. Such proteins are characterized by the presence of a bipartite N-terminal extension consisting of a signal peptide as well as a transit peptide. The exact nature of the targeting process varies depending on the membrane topology of the plastid in question.

In cryptophytes, haptophytes, and stramenopiles, whose plastids are surrounded by four membranes, the outermost membrane is continuous with the nuclear envelope and endoplasmic reticulum (ER) (Fig. 1(d)), and plastid preproteins are first inserted cotranslationally into the ER lumen. The signal peptide is cleaved by signal peptidase and the transit peptide is then used to divert the preprotein from the secondary host cell’s normal secretion pathway and direct it across the remaining plastid membranes. In organisms whose plastids do not physically reside within the host cell’s endomembrane system, such as chlorarachniophytes and euglenids (Table 1), bipartite N-terminal extensions are also used, with plastid proteins presumably being shuttled from the ER lumen to the plastid by vesicular transport. In some cases, host nucleus-encoded proteins must be targeted to the residual cytosol of the engulfed algal cell (the periplastidal space) but not to the plastid itself. In these instances, specific sequence characteristics of the N-terminal end of the transit peptide appear to determine whether or not the protein will be translocated across the remaining plastid membranes.

Number of secondary endosymbiotic events

Determining the number of endosymbioses that have spawned the known diversity of secondary plastid-containing algae has proven challenging. Given that secondary plastids are either of green or red algal origin, a minimum of two endosymbioses must be inferred. However, as many as seven independent events, involving multiple green and red algal endosymbionts, have also been proposed. This discrepancy is based on different interpretations of the evolutionary significance of nonphotosynthetic relatives of the major secondary plastid-containing lineages described above. For example, in addition to possessing multiple photosynthetic groups, the stramenopiles also include many nonphotosynthetic (and plastid-lacking) lineages such as the oomycete plant pathogens. In the case of dinoflagellates, only ~50% of known species are actually photosynthetic, and the most basal lineage of cryptophytes, the genus *Goniomonas*, is an extremely diverse, heterotrophic group whose members do not harbor a plastid. In addition, the chlorarachniophytes and euglenids are evolutionarily deeply embedded within lineages of predominantly nonphotosynthetic groups (Rhizaria and Euglenozoa, respectively).

This “patchy” distribution can thus be explained by invoking either a separate, recent, endosymbiotic event for each secondary plastid-containing lineage, or fewer, more ancient, secondary endosymbioses coupled with extensive plastid loss. Distinguishing between these two possibilities relies on our ability to accurately infer whether or not the phylogenies of plastid and host nuclear genes agree with one another and are consistent with all other available data, such as plastid pigmentation, ultrastructure, and biochemistry. Significant advances have been made in this area, though many uncertainties remain and the topic is actively debated in the primary literature.

Regarding the origin(s) of photosynthesis in chlorarachniophytes and euglenids, current data are most consistent with the idea that their green algal plastids are the product of two separate secondary endosymbioses. Single-locus phylogenies of plastid and nuclear genes typically provide little information about the evolutionary placement of these two lineages relative to one another, but the picture emerging from analyses of concatenated plastid- and nucleus-encoded proteins is that two evolutionarily distinct green algal endosymbionts were taken up independently by the nonphotosynthetic ancestors of the two groups.

Discerning the evolutionary history of photosynthesis in lineages harboring red algae-derived plastids is somewhat more complicated. At one extreme, the “chromalveolate” hypothesis posits a single, ancient secondary endosymbiosis in an ancestor of cryptophytes, haptophytes and stramenopiles (chromists), and dinoflagellates, apicomplexans and ciliates (alveolates). This demands secondary plastid loss in all plastid-lacking lineages specifically related to these groups (eg, ciliates, oomycetes). Alternatively, a separate secondary endosymbiosis could have given rise to the plastids in each of these groups, eliminating the need to invoke plastid loss. Still another possibility is tertiary endosymbiosis, which occurs when a secondary plastid-containing alga is engulfed by a heterotrophic eukaryote. As discussed below, although well known to have occurred in dinoflagellates, the extent to which red algal-derived secondary plastids have spread by tertiary endosymbiosis is unknown.

A variety of data have been brought to bear on the question of congruence between host cell and plastid phylogenies, with mixed results. Plastid gene phylogenies typically do not strongly favor either hypothesis, although such analyses are often hampered by limited taxonomic sampling and artifacts associated with the highly divergent sequences that are found in some of these plastid genomes. Interesting early evidence consistent with the chromalveolate hypothesis came from nuclear-encoded plastid-targeted proteins such as glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Eukaryotic phototrophs typically possess two nucleus-encoded GAPDH isoforms, one noncyanobacterial protein functioning in the cytosol, and a second cyanobacteria-derived protein targeted to the plastid. In chromists, dinoflagellates, and alveolates, the plastid-targeted GAPDH protein is not cyanobacterial in origin, but is instead the product of a duplicated version of the cytosol-localized protein. This phenomenon, referred to as “endosymbiotic gene replacement,” is potentially an important source of rare genomic characters that can shed light on deep evolutionary relationships. However, it has been difficult to rule out the possibility that such genes have evolved in a nonvertical fashion (ie, have been horizontally transferred between unrelated species).

With the increasing availability of complete genome sequences and large expressed sequence tag (EST) and RNA-Seq transcriptome data sets, it is now possible to analyze large data sets of concatenated protein sequences in an effort to better resolve the interrelationships among “chromalveolate” taxa. To date, such analyses have provided support for a close relationship between some, but not all, chromalveolate lineages. Until recently, phylogenetic evidence supported a specific relationship between cryptophytes and haptophytes, but the evolutionary connection between these two groups and stramenopiles was tenuous, despite the results of plastid gene phylogenies and their similar plastid membrane topologies. Recent multi-gene phylogenies have provided mounting evidence for the grouping of SAR (stramenopiles, alveolates, and rhizaria), to the exclusion of cryptophytes and haptophytes. Interestingly, this puts the secondary green plastid-containing lineage Chlorarachniophyta together with two diverse lineages, some of the members of which have secondary red algal plastids. This has implications for the evolution of complex plastids, as additional organelle losses must be invoked if a red algal-derived plastid was present in the common ancestor of SAR.

The similarities in plastid morphology, plastid gene sequences, and plastid protein import machinery suggest that red algal-type complex plastids arose only once during eukaryotic evolution. In its current state, however, the tree of eukaryotes based on nuclear loci has haptophytes and the plastid-lacking, heterotrophic centrohelids branching together as sister group to SAR, while cryptophytes branch within Archaeplastida. If this topology is correct, it rules out the possibility that the single red algal secondary endosymbiosis occurred in the common ancestor of all of these groups. Instead, one or more cryptic tertiary endosymbioses must have occurred to spread red plastids amongst “chromalveolate” taxa. One possibility is that a red alga was taken up by an ancestor of today’s cryptophytes in a secondary endosymbiotic event, followed by spread to haptophytes, stramenopiles, and alveolates by

tertiary and perhaps even quaternary events. Determining the exact sequence of evolutionary events leading to the pattern of red plastid-containing lineages is confounded by the extremely ancient nature of the endosymbioses involved. However, recent evidence does not support the hypothesis of a single, ancient endosymbiotic event in the ancestor of all red plastid-containing lineages, leaving open new possibilities for future work.

Inferring the minimum number of endosymbioses necessary to explain the diversity of secondary plastid-bearing eukaryotes is desirable from the perspective of understanding the processes of gene transfer and protein import. As summarized above, secondary endosymbiosis is very complex at the genetic and biochemical level: each event requires (1) the relocation of hundreds of plastid-derived genes from the primary host nucleus to the secondary host nucleus; (2) the acquisition of a functional signal peptide by each of these genes/proteins; and (3) the adaptation of the existing signal peptide secretion system such that plastid proteins containing bipartite N-terminal leader sequences can be targeted to the plastid.

Conversely, plastid loss would also seem to be difficult. Critics of the chromalveolate hypothesis point out that, in addition to photosynthesis, the plastids of plants and algae are the site of essential cellular processes such as the biosynthesis of isoprenoids and fatty acids, which explains why nonphotosynthetic organisms such as the malaria parasite *Plasmodium* retain a vestigial form of the organelle (the apicoplast). However, evidence for outright plastid loss in the apicomplexan *Cryptosporidium* has come from the presence of cyanobacteria-derived genes of apparent plastid origin in its nuclear genome. In addition, organisms previously thought to be plastid lacking, such as the dinoflagellate-like genus *Perkinsus*, have been found to harbor a remnant plastid. Finally, the discovery of organisms such as *C. velia* and *V. brassicaformis*, unicellular phototrophs that appear to be the closest known relatives of the apicomplexan parasites, has revealed how gene content changes during the transition from a free-living photosynthetic cell to an obligate intracellular parasite. Evidence suggests that gene gains were limited during this transition, while gene losses were frequent during the transition from a free-living alga to an apicomplexan ancestor, and further lineage-specific losses occurred during the diversification of apicomplexans. There is also evidence of proteins present in chromerid genomes that were co-opted for parasitic processes in apicomplexans. In sum, there is a steady stream of new molecular and ultrastructural data to account for when considering the evolutionary history of red algal-type complex plastids.

Nucleomorphs and Their Genomes

As mentioned above, the cryptophytes and chlorarachniophytes are of special interest with respect to the study of secondary endosymbiosis. This is because they are the only two lineages in which the nucleus of the engulfed algal cell still exists inside the new host. These remnant nuclei (nucleomorphs) lie within the residual cytosolic compartment of the alga, which is located between the outer plastid membrane and the primary algal outer membrane (Fig. 1(d)). The nucleomorph genomes of cryptophytes and chlorarachniophytes have been completely sequenced and are surprisingly similar in basic structure and composition. This is intriguing given that they evolved independently of one another (the cryptophyte plastid is derived from a red alga, while the chlorarachniophyte plastid has a green algal ancestry). Analysis of nucleomorph genome sequences has provided fascinating insights into the consequences of nuclear genome reduction and compaction.

The first nucleomorph genome to be analyzed in detail was that of the model cryptophyte *Guillardia theta*. The complete *G. theta* genome comprises three small chromosomes totaling a mere 551 kbp. Each of the three chromosomes is capped with unusual telomeres ([AG7]AAG6A)₁₁ and near-identical subtelomeric ribosomal DNA (rDNA) repeats. As is often the case with genomes of endosymbiotic origin, the *G. theta* genome is compositionally biased (~75% AT in single-copy regions, ~55% in the repeats) and its gene density is high (~1 kbp/gene). Of 465 protein-coding genes, only 30 encode plastid-targeted proteins, counter to initial speculation that nucleomorph genomes would be enriched in genes related to photosynthesis and plastid-related processes. Instead, the bulk of the *G. theta* genome encodes proteins involved in core eukaryotic processes such as transcription, translation, and protein folding/degradation. These proteins presumably function to maintain the nucleomorph genome, express its “housekeeping” genes, and enable it to produce the few proteins that it continues to target to the plastid. The *G. theta* gene repertoire is in fact far from complete and it is already missing numerous genes for essential cellular processes such as DNA replication as well as important structural proteins (eg, actin). Sequencing of the *G. theta* nuclear genome revealed ~2400 proteins that were predicted to function in the nucleomorph or remnant algal cytosol, and that are targeted post-translationally. This explains the whereabouts of many essential genes lacking from the nucleomorph genome.

The second cryptophyte nucleomorph genome to be sequenced was that of *Hemiselmis andersenii*, an organism quite distantly related to *G. theta*. At 572 kbp, the genome is similar in size and coding capacity to that of *G. theta* but possesses a number of interesting differences. The *H. andersenii* nucleomorph telomeres are (GA17)_{4–7}, very different from those of *G. theta*, and only three of the six chromosome ends possess intact rDNA operons, the other three harboring stand-alone 5S rDNA loci. Most unexpected is the complete absence of spliceosomal introns and genes for splicing RNA and proteins in the *H. andersenii* genome. This contrasts with the *G. theta* genome, which possesses 17 small introns and encodes a variety of proteins that make up the spliceosome, including the splicing “platform” prp8. Together with a few highly reduced microsporidian parasite genomes, the *H. andersenii* genome represents a rare instance of complete intron loss in a nuclear genome, presumably as a result of intense evolutionary pressure to reduce genome size.

A further two cryptophyte nucleomorph genomes were published in 2010 and 2012. *Chroomonas mesostigmatica* and the non-photosynthetic *Cryptomonas paramecium* contain the largest (703 kbp) and smallest (486 kbp) cryptophyte nucleomorph genomes, respectively. Despite the differences in size, their genome architecture and total gene number are in line with one another and the

two previously described cryptophyte nucleomorphs. The relatively large *C. mesostigmatica* nucleomorph genome contains 32–61 more genes than the other three cryptophyte nucleomorphs. It also has slightly longer proteins, with an average of 357aa versus 289aa, 312aa and 338aa in the other three genomes. However, gene number and length do not account for the discrepancy in nucleomorph genome sizes. The *C. mesostigmatica* genome contains many short sequence repeats as well as multi-copy genes, highly unusual for a nucleomorph genome. The single largest contributing factor to cryptophyte nucleomorph size variation seems to be non-coding DNA content, with significantly longer intergenic spacers in *C. mesostigmatica*. The increased intergenic sizes have further implications for this genome. *C. mesostigmatica* seems to have a lower degree of synteny shared with the other three species than they do with one another, possibly as a result of more frequent recombination facilitated by larger non-coding regions. Some of these syntenic breaks coincide with the position of protein degradation genes in the other species, suggesting a recombination-mediated gene loss mechanism. The presence of small ORFs in syntenic positions to full-size genes in the other species is evidence of ongoing genome decay and gene loss in cryptophyte nucleomorphs.

Patterns of nucleomorph gene content variation in cryptophytes provide insight into the reductive processes that take place during endosymbiosis. Evidence of specific biochemical pathways being uniquely lost in individual species can be found. For example, many of the 24 genes missing from the non-photosynthetic species *C. paramecium* have plastid-related functions. Similarly, the intron-devoid *H. andersenii* genome lacks seven genes whose functions are associated with splicing. Surprisingly, the relatively large *C. mesostigmatica* nucleomorph seems to have completely lost an important protein degradation pathway, as all proteasome subunit genes are missing, a trait shared with the Chlorarachniophyte *Bigeloviella natan*. Until more host nuclear genomes are sequenced we cannot rule out the possibility of nucleomorph to host gene transfer, however, current evidence does not support this. Interestingly, the exact same set of 31 plastid-associated proteins is found in the three photosynthetic cryptophyte nucleomorph genomes, with a subset being present in *C. paramecium*. This suggests that these plastid proteins may not be capable of being transferred to the host nucleus, and that this reduced set was likely in-place prior to the diversification of modern-day cryptophytes. The presence of these plastid proteins likely explains, at least in part, the reason for nucleomorph persistence in cryptophytes (see below).

The nucleomorph genome of the chlorarachniophyte *B. natans* is 373 kbp in size, significantly smaller than that of any known cryptophyte nucleomorph genome. Like the cryptophyte nucleomorphs, the *B. natans* genome consists of three small, AT-rich chromosomes, each with subtelomeric rDNA operons. Remarkably, the nucleomorph genomes of cryptophytes and chlorarachniophytes have converged upon the same karyotype and basic chromosome structure despite being derived from different algal endosymbionts, each of which presumably possessed dozens of nuclear chromosomes. The significance of this convergence is unknown. The *B. natans* nucleomorph encodes 293 protein genes, only 17 of which are involved in photosynthesis. Unlike the situation in cryptophytes, introns are abundant in the nucleomorph genes of *B. natans*, with an average of ~3 introns/gene. The introns themselves are, however, greatly reduced in size, being between 18 and 21 bp in size, the smallest spliceosomal introns known. Overall, the functional distribution of nucleomorph genes in *B. natans* is similar to that seen in cryptophytes with the exception of genes involved in RNA metabolism, for which *B. natans* is somewhat enriched. While the *B. natans* host nuclear genome has acquired ~1000 endosymbiont nuclear genes whose products are posttranslationally targeted, this is substantially fewer than in *G. theta*. Relative to *B. natans*, the *G. theta* nuclear genome appears to be enriched in genes for PPC and nucleomorph-targeted proteins functioning in protein degradation, RNA degradation, protein folding, and metabolic enzymes. On the other hand, *B. natans* encodes more nucleomorph-targeted spliceosome components, in line with the presence of many introns in the *B. natans* nucleomorph genome itself.

Three additional chlorarachniophyte nucleomorph genomes have been sequenced in recent years. This provided the data necessary for comparative genomics of green algal derived endosymbiont nuclei. As expected, the nucleomorph genomes of *Lotharella oceanica*, *Lotharella vacuolata*, and *Amorphochlora amoebiformis* are composed of three chromosomes and have GC contents of 25–35%. *L. oceanica* has the largest chlorarachniophyte nucleomorph genome at 612 kbp, with *L. vacuolata* a distant second at 432 kbp. The nucleomorph genome of *A. amoebiformis* is 374 kbp, nearly identical in size to that of *B. natans* (373 kbp). Similar to cryptophytes, nucleomorph genome size variation among chlorarachniophytes correlates with the length of intergenic spacers. However, frequent gene duplication is the main reason for larger genome sizes in *Lotharella* species. Several duplicated genes are even shared between *L. vacuolata* and *L. oceanica*, consistent with gene duplications having occurred prior to the diversification of *Lotharella* species. In addition, a large sequence consisting of 45 ORFs was found within the subtelomeric repeats of *L. oceanica* but not in *L. vacuolata*, explaining much of the genome size difference between the two closely related species. While nucleomorph subtelomeric rDNA operons are highly conserved, it appears that an inversion has reversed the orientation of the *B. natans* rDNA operons relative to those in other chlorarachniophyte nucleomorph genomes.

The number of non-redundant protein-coding genes in the four sequenced chlorarachniophyte nucleomorphs ranges from 288 to 338. However, gene duplications have had a large effect on the total number of genes in *Lotharella* species, with 596 genes in *L. oceanica*, 319 in *L. vacuolata*, 300 in *A. amoebiformis*, and 288 in *B. natans*. There is an 86% overlap in genes with predicted functions between the chlorarachniophyte nucleomorphs, more than the proportion shared among cryptophyte nucleomorphs. Also, the four chlorarachniophyte nucleomorph genomes share the same set of 17 plastid-associated proteins. This suggests that the reduced set of plastid genes was present prior to diversification of the lineage, in line with the situation in cryptophytes. There is evidence of a small number of lineage specific gene losses in chlorarachniophyte nucleomorphs, and no evidence of recent nucleomorph-to-nucleus gene transfer. There are also many lineage specific hypothetical nucleomorph genes. These genes have nevertheless been found in syntenic positions to genes of known function in other species, raising the possibility that they have simply diverged beyond the point where their functions can be predicted. Finally, although a high level of synteny is typical of

nucleomorphs and other reduced genomes, there appears to be smaller syntenic blocks in chlorarachniophyte nucleomorphs than in cryptophytes, suggesting higher recombination rates. This is especially true in *Lotharella* species that contain more duplicated regions than nucleomorphs in other species.

One of the most fundamental, and unanswered, questions regarding nucleomorph evolution is why they exist at all. By definition the process of secondary endosymbiosis includes a “transition period” during which the nucleus of the algal endosymbiont resides within its residual cytosolic compartment and continues to service its plastid. However, other than cryptophytes and chlorarachniophytes, the nucleomorphs of all other secondary plastid-containing lineages have completely disappeared, having transferred all of their essential genes to the secondary host nucleus. There are two main possibilities for the persistence of nucleomorphs. First, it is possible that not enough time has elapsed for nucleomorph-to-host-nucleus gene transfer to go to completion and the nucleomorph genomes (and nucleomorphs) of cryptophytes and chlorarachniophytes will eventually disappear. Alternatively, there may be barriers to the successful transfer of the remaining genes in the cryptophyte and chlorarachniophyte nucleomorph genomes, as has been proposed to explain the persistence of mitochondrial and plastid genomes.

There are currently not enough data to determine with confidence which of these two possibilities is most likely, though the comparison of the gene content of the nucleomorph genomes of the cryptophyte *G. theta* and the chlorarachniophyte *B. natans* is consistent with the former scenario. There is very little overlap in the suite of plastid proteins encoded in cryptophyte and chlorarachniophyte nucleomorph genomes, suggesting that nucleomorph to host nucleus gene transfer could essentially be a random process. The presence of the same set of plastid proteins within each of these lineages is most likely the result of strong reductive processes early in the evolution of the host–endosymbiont relationship, prior to the diversification of each lineage.

The completion of several cryptophyte and chlorarachniophyte nucleomorph genomes has provided insight into the patterns of gene content variation among nucleomorphs. The core set of housekeeping genes is quite well conserved, with the majority of gene content diversity involving hypothetical genes. Some lineage-specific losses of core genes have been found, most notably in cryptophytes. Interestingly, recent analysis of the nuclear genomes of *G. theta* and *B. natans* showed no evidence of recent EGT from the plastid or nucleomorph to the host nuclear genome. Several cases of mitochondrion-to-nucleus transfer were found in *G. theta* and *B. natans* (involving short DNA fragments), evidence that EGT can still occur in these organisms. The apparent absence of recent plastid and nucleomorph EGTs can be explained by the “limited transfer window” hypothesis, which posits that there is a greater chance of EGT from multi-copy organelles because lysis of a single-copy organelle would presumably be lethal. Importantly, *G. theta* and *B. natans* each contain a single plastid–nucleomorph complex per cell, whereas multiple or reticulated mitochondria are present in the cytosol, making mitochondrial lysis and DNA transfer possible. While cryptophytes have lost some genes involved in core eukaryotic processes, the functional significance of these losses is unclear, and it would seem that nucleomorph reduction is nearing an endpoint, at least in species with a single nucleomorph per cell. Additional nucleomorph and nuclear genome sequence data from diverse cryptophytes and chlorarachniophytes will be needed to more rigorously test the limited transfer window hypothesis for the persistence of nucleomorphs.

Tertiary Endosymbiosis

Algae with secondarily-derived plastids are the result of eukaryote–eukaryote fusions that lead to increased genetic and morphological complexity. These cells are unusual in containing genes from two phylogenetically distinct eukaryotes and two prokaryotes. However, even more complex symbiotic mergers exist. In serial secondary events, a primary alga is taken up and replaces the current secondary plastid of the cell. This is known to have occurred in certain dinoflagellates. Tertiary endosymbiosis is the uptake of a secondary plastid-containing alga by a heterotrophic host. In order for the tertiary plastid to be maintained and inherited, genes must be transferred from the secondary host to the tertiary host nucleus. Many of these genes are likely of cyanobacterial origin, and have taken a convoluted evolutionary path from a bacterial genome through two eukaryotic intermediates, to finally end up in the tertiary host nucleus. The degree of endosymbiont streamlining and level of integration with the host varies greatly in different tertiary and serial secondary endosymbioses, as will be discussed below.

Dinoflagellates are notorious for their frequent loss and uptake of endosymbionts. The types of endosymbiotic events known within this lineage include: secondary or cryptic tertiary endosymbiosis of a red alga or red algal-derived secondary plastid (as in peridinin plastids), serial secondary endosymbiosis of a green alga, and at least three tertiary endosymbioses involving haptophytes, diatoms, and cryptophytes. With the exception of nucleomorphs, secondary endosymbionts typically lose most cellular and genetic features, leaving just the plastid with one or two additional membranes. However, in the more recent tertiary events the endosymbiont is remarkably unreduced. In so-called “dinotoms,” the diatom endosymbionts retain their nuclear genomes and mitochondria. This is an extremely rare case of a cell containing mitochondria of two distinct origins. On the other hand, green algal and haptophyte-derived endosymbionts found in other dinoflagellate lineages appear to have lost their nuclei and mitochondria.

Integration and gene transfer in tertiary endosymbiosis

Sequencing of multiple dinoflagellate peridinin plastid genomes has revealed several unusual and unique features. Dinoflagellate plastids contain fewer than 20 genes, encoded individually or in small numbers on plasmid-like circular chromosomes. This is in contrast to most plant and algal plastid genomes that have a single circular chromosome encoding 60–250 genes. Therefore, more plastid genes have been transferred to the dinoflagellate host nucleus than in other algal lineages. In the chromerid algae, close photosynthetic relatives of dinoflagellates and apicomplexans, we see evidence of more typical plastid genome architecture, suggesting that the ancestral peridinin plastid looked like other red and green algal derived plastids. In addition, dinoflagellate

plastid sequences undergo transcript processing in the form RNA editing and polyU addition. The unconventional nature of dinoflagellate peridinin plastids creates a unique situation which allows comparisons with subsequent endosymbionts.

Tertiary endosymbiotic events typically involve the replacement of a secondary plastid, adding an additional level of complexity in terms of plastid protein redundancy. Whether the secondary plastid is retained during the transition to a tertiary or serial secondary derived plastid, or is lost prior to the uptake of the “replacement” organelle, is unknown. However, there is some evidence of dinoflagellate peridinin plastid proteins with predicted targeting to haptophyte and green algal-derived plastids. This mixing of proteins from different sources suggests the evolutionary co-existence of the two organelles during plastid replacement. Proteins of peridinin plastid origin have also been found in dinotom host genomes. However, homologous copies in the diatom endosymbiont nuclear genome appear to encode proteins functioning in the plastid, while those encoded in the host nucleus lack targeting signals. This provides further evidence that dinotom tertiary endosymbionts are not as tightly integrated with their hosts as are the haptophyte and green algal endosymbionts.

Dinoflagellate peridinin plastid genes undergo RNA editing and polyU tail addition, processes not typically associated with plastids. Intriguingly, haptophyte-derived tertiary plastid transcripts also show these types of processing, while free-living haptophyte secondary plastids do not. On the other hand, no evidence of transcript processing has been found in dinotom and serial secondary green algal plastids. This suggests that the level of endosymbiont integration may be affected by the use of processing pathways associated with the original peridinin plastid. Also, there is evidence of a haptophyte tertiary plastid gene located on a minicircle chromosome, similar to the genome architecture found in other dinoflagellate plastids. Perhaps transcript processing provides a means of compensating for high mutation rates and changes in genome structure that would otherwise disrupt essential gene expression. This may even contribute to more frequent permanent establishment of endosymbionts, thus helping to explain the prevalence of plastid replacements in the dinoflagellate lineage. Many of the evolutionary steps involved in tertiary endosymbiosis are still unclear, but the study of dinoflagellate endosymbionts that exhibit differing levels of integration has begun to provide some answers.

Secondary endosymbiosis has had a significant impact on the evolution of eukaryotes, in particular the spread of photosynthetic capabilities to a huge diversity of organisms. Recent genomic and transcriptomic analyses have provided important insight into the integration between endosymbionts and their hosts. However, much of what happens between the initial association of two eukaryotes and the end product – a fully integrated plastid – remains a mystery. More recent serial secondary and tertiary events in dinoflagellates are just starting to reveal what sorts of endosymbiotic intermediates are possible, with a wide range in the level of genetic and cellular integration being seen. The clear cases of tertiary endosymbiosis observed in dinoflagellates also raise the possibility that one or more cryptic tertiary endosymbioses have taken place during eukaryotic evolution, and are responsible for the present discrepancy between host cell phylogeny and plastid evolution. Despite substantial progress in the age of comparative genomics, there is still much to learn about the origin and spread of red algal-derived plastids across the eukaryotic tree.

Glossary

Cable bacteria Multicellular filamentous forms of bacteria that are capable of long range electron transport between the sulfide-rich zoner and the oxic zone in sediments.

Diffusion The process whereby molecules tend to distribute themselves to uniform concentration. This often dominates sedimentary habitats, where the environment is physically stabilized, and the only input of oxygen is via diffusion from oxygen-rich environments above the sediments.

Extracellular electron transport (EET) The process whereby some bacteria and archaea can oxidize and/or reduce insoluble redox-active components outside the cell wall, allowing long-distant electron transport to otherwise unavailable compounds or cells.

Layered microbial community (LMC) The community organization often seen in sediments, in which electron acceptors, such as oxygen, are consumed, and then other electron acceptors (nitrate, manganese, iron, sulfate, carbon dioxide) are used in sequence, resulting in microbial (and chemical) layers due to the activities of microbes present.

Macrofauna Eukaryotic multicellular organisms that are found in many sediments. These organisms take advantage of the energy-rich sediment environment, feeding on the prokaryotic biota. They also impact the physically stabilized sediments by pumping oxygen-rich water through the sediments, thus disrupting the diffusion-dependent layers and gradients.

Pore water The water found in the spaces between sediment particles. Pore water is the most commonly used parameter to judge the chemical reactions occurring in sedimentary niches.

Sediment A water-saturated, physically stabilized environment that obtains input (and grows) via the addition of material from above. In sediments located in shallow water, input can also occur via the activity of photosynthetic microbes within the sedimentary niche.

Abbreviations

C _{org}	organic carbon
EET	extracellular electron transport
LMC	layered microbial community
PAR	photosynthetically active radiation
SRB	sulfate-reducing bacteria
SRR	sulfate reduction rate

Defining Statement

The sedimentary niche is one of the largest ecosystem on Earth, harboring ~4PgC and 3×10^{29} cells (Kallmeyer et al., 2012). The processes that occur in these water-saturated, physically stabilized niches often lead to the formation of chemical gradients or layers, which can be used to infer modern and/or ancient sedimentary microbial processes.

Introduction

What is Sediment?

For our purposes, active sedimentary environments are defined as the underlying matrix of aquatic environments in which sedimentary (depositional) processes occur, and in which some form of deposit (sediment) accumulates with time via input of particles from the overlying water. Thus, the entire ocean bottom, excluding rocky outcrops and the active wave-breaking zone, in which sediments seldom permanently accumulate, is a sedimentary environment, as are virtually all lake bottoms. Rivers can

This article is an update of K.H. Neelson, W. Berelson, Sediment Habitats, Including Watery, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 350–360.

Fig. 1 Some of the fundamentals of the sedimentary niche. While simple in comparison to complex soil environments, the sediments have a number of important properties that define them. Both organics and inorganics are constantly removed to the sediment water interface (SWI) by sedimentation. Organics are removed by respiration. In well mixed waters this is oxic respiration, but if poorly mixed, oxygen is consumed and anoxic respiration prevails, as shown. In the sediments, with limited mixing, anoxic respiration prevails, and electron acceptors are primarily supplied by addition from above. If irrigation by eukaryotic worms occurs, gradients of oxidants can be seen emanating outwards from the worm tubes.

accumulate sediments, but depending on the dynamics of the river, these deposits may be short-lived and difficult to predict and/or define. Not all sediments are alike, of course, and their variations are subject to several key factors: (1) the chemical nature of the overlying water; (2) the impact of light (photosynthetically active radiation or PAR) on the sediment surface; (3) the type and amount of organic input to the sediments; and (4) the type and amount of inorganic input to the sediments (Fig. 1).

One of the important properties of sediments relates to the fact that the environment is physically stabilized: That is, there is minimal mixing or convection, and chemical transport to and from the niche is dominated by diffusion. For example, if the oxygen is consumed within a given sediment, then it must be supplied from above by diffusion, and this interplay is extremely important in defining the chemistry and microbiology of the sedimentary niche.

Where are Sediments Found?

Sediments are found at the bottom of virtually every body of water: streams, rivers, lakes, and throughout the ocean. Even in the absence of any obvious sedimentary source, the mean global dust fallout from the atmosphere alone can generate sediment accumulation rates of one or more millimeters per kiloyear. Thus, any body of water on this planet will accumulate sediments, and as material falls through water, it can accumulate a variety of 'hitchhikers' including prokaryotic and eukaryotic cells, as well as organic and inorganic materials (metals, minerals, clays, nutrients, etc.).

What are Sediments Composed of?

Dust is the source of ~35% of sediment accumulating in the global ocean: Such dust-dominated sediments are known as red clay deposits, and they are abundant in the deepest ocean and sites furthest removed from continental land masses. In contrast, about

50% of oceanic sediments are termed biogenic (SiO_2 or CaCO_3) insofar as the dominant sediment particles are mineral grains formed via precipitation (biomineralization) by either diatoms and/or radiolarians (SiO_2), or coccolithophores and/or foraminifera (CaCO_3). These mineral grains, like dust particles, settle through the water column and accumulate an array of 'hitchhikers', much like an elevator headed down a skyscraper. Lake sediments and some nearshore oceanic sediments tend to be dominated by particles either carried by rivers or eroded along the shore. These sediments, termed terrigenous, tend to vary considerably both in time and in space, are subjected to mass movement during storm events, and are prone to move offshore and downslope via current dispersion and turbidity flow. When viewed from afar, sediments seem to be slowly and constantly accumulating, but, in fact, the distribution of sediment types and amounts has varied considerably throughout geologic time, revealing past changes in tectonic activities, climate, and global (especially oceanic) productivity.

The Diversity of Sediments

The Importance of Overlying Water

As opposed to soils, which often alternate between wet and dry states, sediments are constantly wet, and are commonly described by the water that overlays them: marine sediments and lacustrine or freshwater sediments. Superimposed on the marine/lacustrine division is the issue of light. Sediments in shallow water can differ drastically from those in deeper water because of the impact of photosynthesis that can occur in the sediments themselves: Deepwater sediments are nearly always the recipients of photosynthate (photosynthetically produced organic carbon (C_{org})) from above, rather than internal primary production. Since photosynthesis can also be a source of oxygen, the shallow water sediments are prone to being oxic in the daytime, and exhibiting strong day/night differences in terms of redox chemistry, something not seen in deepwater sediments.

Of course, not all lake sediments are overlain by 'fresh' water – their chemistries may range widely in pH, salinity, and nutrient chemistry, and in each case, this leads to a different set of conditions in the sediments – conditions that alter the microbial ecology of the sediment basin. Examples of such environments include alkaline lakes such as Walker Lake, NV, alkaline hypersaline lakes such as Mono Lake, CA, and hypersaline lakes such as the Great Salt Lake, UT, and the Salton Sea in the Southern California Desert.

In general, lacustrine sediments receive higher levels of organic input than do marine sediments, and as a result they become anoxic rather quickly (within centimeters or less of the sediment water interface). In many cases, because lakes are often poorly mixed, the bottom water overlying the sediments can itself be anoxic, leading to sediments lacking macrofauna or other eukaryotes.

Marine Sediments

Marine sediments, with a few notable exceptions, are characterized by a sediment–water interface that includes oxic water overlying sediments that at some level become anoxic. This is because oceanic circulation constantly supplies the deep ocean with oxygen-rich water from the high latitudes, and keeps the deep ocean water often more oxygen-rich than the near-surface waters. Notable exceptions to this 'rule' include: (1) the Black Sea, which is isolated from oceanic circulation, and is thus anoxic for most of its depth; (2) marine basins, such as the Cariaco Trench, which is also isolated from deepwater flow and mixing due to the presence of a structural sill that inhibits mixing and results in the water becoming anaerobic far above the sediment–water interface; and fjords in which a freshwater layer forms over marine water due to riverine flow coupled with a sill at the fjord entrance. Other, smaller anoxic (lacking oxygen) basins include Saanich Inlet, Canada; Gotland Deep, Baltic Sea, and the Orca Basin, Gulf of Mexico.

As a rule, marine sediments are dominated by the sulfur cycle, due to the fact that seawater usually has $\sim 28 \text{ mmol l}^{-1}$ sulfate, which, after oxygen is depleted, becomes the major electron acceptor. Thus, marine sediments are notorious for sulfide production and for internal sulfur cycling (reduction–oxidation–reduction, etc.). Except in cases of very high input of organic matter, sulfate depletion does not occur, and thus, biological methane production in marine sediments is usually not a major process.

Lacustrine Sediments

Lacustrine (i.e., having to do with lakes) sediments vary widely with regard to the oxidation state of the overlying water. In many lakes the waters are well mixed, and very ocean-like in terms of being permanently oxic, while others range from being seasonally stratified (and thus having anoxic bottom waters for some portion of the year) to the so-called meromictic (permanently stratified) lakes, with bottom water that never sees oxygen in abundance. In addition to this rather simple delineation are those sediments beneath lakes that may have chemistries more reminiscent of oceanic environments, such as the Salton Sea, or evaporitic lakes, where salinity can be quite high, and sulfate concentrations that are similar to, or even higher than, those found in the ocean.

In marked contrast to marine sediments, where sulfate reduction dominates, lake waters are typically very low in sulfate, and lacustrine sediments are usually dominated by methane production. Sulfate concentration in most lacustrine sediments is in the tens of micromolar range (0.1%–1% of the level in seawater), and when it is depleted, carbon dioxide becomes the major electron acceptor, and methane is the major product. Thus, in terms of sediments as microbial habitats, one might regard sulfate concentration as one of the key variables regulating the microbial metabolism and biogeochemical cycling.

Sampling and Description of Sediments

Pore Water

Pore water is what it implies: the interstitial water occupying the spaces between sediment particles (Fig. 1). Pore water chemistry is commonly the parameter that is measured to characterize a sedimentary environment in terms of the microbial ecology of these environments, and is arguably the single most important property of sediments to measure. Pore waters can be obtained by sectioning and centrifuging sediment core samples, by whole-core squeezing, by sucking water out using Rhizon fileters, or by allowing diffusion into chambers called 'peepers' that are allowed to equilibrate with the sedimentary environment. Sectioning and squeezing are usually performed in an anaerobic glove box to avoid effects of oxygen on sensitive components like sulfide or ferrous iron, but even with this precaution, results can be quite variable. Squeezing subcored sediment and expressing the pore waters directly into syringes minimize handling, and often yield much more reproducible results with regard to non-surface-reactive compounds. Peepers, while yielding high quality data, often need to be equilibrated for long periods, not compatible with many field expeditions. Another approach to obtaining pore water chemistry profiles is that of the use of microelectrodes, which directly measure the concentrations (activities) of certain species. This method allows for very high spatial resolution, rapid data acquisition, and high reproducibility. However, the electrodes are solute specific, often very expensive, and can be quite fragile.

Porosity and Tortuosity

Interlinked with the concept of pore water nutrient chemistry are two other key sediment properties: porosity and tortuosity. The porosity is a measure of sediment water content, defined as the volume of pore space per unit volume of total sediment. Typical surface ocean or lake sediments will have a porosity exceeding 80% (0.80); coarse-grained sediment will have a lower porosity than fine-grained sediment (as clays tend to stand on edge and create large porous volumes); and sediment porosity will decrease with depth due to compaction. Tortuosity describes the path a molecule or any other solute must take in order to move from point A to B within a sediment column. Because sediment grains come in the way, the distance between A and B becomes a tortuous path with a length greater than the straight line between points. The ability for grains to compact and hence move 'down' relative to a static water column provides a mechanism for microbes associated with certain mineral horizons to be translocated within the sediment column – this process is termed pore water advection.

Sediment Properties

Redox Budgets of Sediments

Sediments accumulate as material arrives at the floor of an aqueous body carrying a load of C_{org} associated with the inorganic matter. The source of the C_{org} can be productivity within the water or it can be transported in from the continents by erosional processes. Insofar as there is no known sterile body of water on the earth's surface (albeit some ponds subjected to extreme metal loading may be near to being sterile), there will always be this association of adsorbed C_{org} and microbes with sediments.

Sediments can also carry a certain oxidizing potential, most often as particulate iron oxyhydroxides (FeOOH) but also manganese oxides (MnO_2). Terrigenous-dominated sediments have the largest quantity of this solid-phase oxidant, typically 4–7 wt% Fe, whereas Mn might constitute up to 0.1% of sediment mass. While there is no 'typical' C_{org} content of sedimenting particles because this parameter will depend on the productivity of the surface ocean or lake, coastal ocean sediments settle to the seafloor with a C_{org} content of 5–10 wt% and many deep-sea sediments settle to the seafloor carrying 3–5 wt% C_{org} . As an example of an electron budget for sediments, assume that particulate material falling to the coastal ocean seafloor is 50% terrigenous and 50% biogenic – the terrigenous material carries 5 wt% Fe as FeOOH and the sedimenting material contains 10 wt% C_{org} (all reasonable values). Such a sediment will be carrying an oxidizing potential (electron acceptors) in deficit of the total reducible load by 2 orders of magnitude! As illustrated here, the reduced load of settling particles is typically much greater than the oxidizing potential of the solid phase, hence the importance of dissolved oxidants and their utilization by heterotrophic prokaryotes in sediment diagenesis.

As indicated by the abovementioned example, an important part of the sedimentary redox budget relates to the dissolved oxidants in the overlying and interstitial spaces. Most sediments are overlain by oxic water, providing ~ 200 – $400 \mu\text{mol l}^{-1}$ oxygen (depending on salinity and temperature), and minor amounts of nitrate and CO_2 . In sediments of high organic content (and high microbial activity), CO_2 and other oxidants are generated in situ, further complicating the matter. The major source of oxidizing power in sediments originates from solutes within the overlying water column. Sulfate (SO_4^{2-}) is perhaps the defining redox (and microbiological) difference between marine and freshwater sediments. It is the major oxidant in marine systems, being present in oceanic waters at a concentration of $\sim 28 \text{ mmol l}^{-1}$ ($100 \times$ the concentration of oxygen and 4 times the number of electrons to be accepted makes sulfate 400 times more potent than oxygen as an oxidant in marine waters), yet often at only $\sim 50 \mu\text{mol l}^{-1}$ in freshwater systems. Thus, the chemical reduction of a variety of sulfur species (sulfate, elemental sulfur, thiosulfate) dominates marine sediments, and is comparatively absent in freshwater sediments, which tend to be dominated by methane production as the final redox activity. The end-member of sulfate reduction, H_2S (S^{2-}) can strongly impact the cycling of both iron and manganese through the formation of insoluble iron sulphides, on one hand, and the reduction of Mn oxides (MnO_2) to soluble Mn^{2+} .

Microbial Input to Sediments

Particles arrive at the sediment–water interface carrying a microbial community. Counts of bacteria on sedimenting particles in the ocean yield a wide range in values (1×10^5 – 1×10^{10}) bacteria per gram resulting in upper surface layers of sediments usually harboring about 10^7 – 10^9 microbes per gram of sediment. Typically, the bacterial density on sedimenting particles exceeds the bacterial density within sediments. However, the biomass of these particle-associated microbes is much less than the biomass of organic matter associated with the particles, with the prokaryotic community contributing typically 3% or less of the total C_{org} burden.

Sediments as Habitats for Microbes

Sediment Properties Relevant to Microbial Ecology

From the point of view of microbial ecology, sedimentary environments are inextricably linked by the facts that they are (1) continuously wet and (2) physically stabilized – that is, the dynamics of the sedimentary environments are defined by diffusion and advection, and not by convection and turbulence more characteristic of the water column. While sediments and soils are often considered to be similar, from a microbiological perspective, they are in fact quite different. Soils are subject to constant changes in wetting and drying, often with extreme dehydration being part of the niche description. In addition, soils lack the constant deposition of new material from above that is so characteristic of sedimentary systems, which are built from above. While diagenetic changes occur within sediments as a result of microbial activity, the primary inputs of material and energy are supplied from above. Soils, on the contrary, are strongly impacted by inputs from within – usually supplied by roots of plants, or decaying plant matter. To some extent, then, sediments can be viewed as much simpler and more predictable environments, once the key variables noted earlier have been characterized (Table 1).

Perhaps one of the most relevant properties of sediments, and one that greatly increases their diversity (and makes them somewhat unpredictable), is that they are composed of particles (clays, minerals, detritus, etc.), and these particles are excellent habitats for microbes and the places where biofilms form. Thus, the biomass in sediments often exhibits a rather nonuniform distribution of microbial biomass, with some particles being covered with thick biofilms, and others being rather devoid of microbes. This nonrandom distribution must surely be of great importance in influencing the way(s) that microbes interact with the geochemistry of the sedimentary niche, and represents one of the great intellectual challenges to understanding the sedimentary niche.

Microbial Abundance in Sediments

Surficial sediments (those near the sediment–water interface) are typically rich in microbes present because of the energy available in the sediments. As mentioned earlier, typical surface sediment numbers have resident prokaryotes that reach numbers on the order of 10^9 per cm^3 of sediment. Yet these are sediments located near organic C inputs, such as coastal environments. Sediments located far from the continents and beneath low productivity surface waters (like the central South Pacific) have on the order of 10^6 cells per cm^3 .

Table 1 Comparison of major properties of sediment and soil environments

<i>Sediments</i>	<i>Soils</i>
Input primarily from above via sedimentation: clay particles, minerals, and microbial biomass	Input from within: plant roots (photosynthesis and nutrient transport), decaying cellular material (e.g., roots) Some accumulation via wind-blown particles (dust and minerals)
Permanently wet – no airspaces	Alternately wet and dry cycles
Electron acceptors rapidly used up	In dry periods, airspaces are present over all oxic soils
Anoxic zone usually shallow	
Because of anoxia, eukaryotes are rare	Because of airspaces, abundance of eukaryotes (nematodes, protists, and fungi)
Dominated by bacteria and archaea	
Primarily controlled by diffusion	Primarily controlled by mixing (plant roots, fungi, nematodes, small eukaryotes, and water flow during wet periods)
Eukaryotes not common except at surface	
Characterized by chemical layers due to consumption of nutrients and production of products (at rates faster than they can diffuse)	Layers are rare, though occasionally present due to wind-blown events (e.g., clay particles) During wet periods, anoxia is common, and layers can form
Gradients that form tend to be simple, 2-dimensional gradients, unless disrupted by bioturbation	Gradients can form around particles, and can be seen as complex 3-D gradients Much less predictable

One can imagine that such bacteria- and organic-rich environments lead to a rapid depletion of oxygen, and this in fact is a nearly universal feature of sediments. Depending on organic matter input, the so-called oxic–anoxic interface will be present as a result of aerobic activity, rendering the remainder of the subsurface an anoxic environment. Thermodynamic ‘logic’ then prevails, and the other available oxidants are consumed in order, with each oxidant providing a measurable chemical layer as it is consumed.

Generation of Chemical Gradients by Microbial Activities

Dr. Robert Berner of Yale University was the first to describe the succession of chemical reactions that occur when various common oxidants react with C_{org} in sediment. The succession is based on the free energy derived from each reaction; the oxidants are those commonly found in aqueous solutions or associated with sediment solid phases. The succession of reactions that are seen in pore water profiles is the result of microbial metabolism leading to the accumulation of products, or the consumption of reactants at rates greater than they can be removed or supplied by diffusion. The succession is readily seen in pore water chemistry, and it occurs as different oxidants, used in the free energy succession, are sequentially depleted (see Fig. 1). The free energy paradigm applies to freshwater sediments as well, with the major difference relating to the paucity of sulfate in freshwaters. Hence, sulfate reduction is a minor process in freshwater sediments, where the transition to methane production occurs more rapidly than in seawater.

The cascade of oxidants involves both reactants and products of C_{org} respiration. For example, the oxidation of organic matter with oxygen yields both CO_2 (which can serve as an oxidant in some reactions) and nitrate, as organic NH_3 is oxidized. These product oxidants are also utilized in the cascade sequence of free energy such that even in sediments underlying water containing no nitrate, nitrate can be one of the oxidants utilized by sedimentary heterotrophs.

The succession of geochemical profiles implies that sedimentary bacteria adhere strictly to the ‘rules’ of thermodynamic energetics. The structure of geochemical profiles obtained from pore water analyses generally supports this argument. However, one misguided assumption associated with the layered microbial community (LMC) paradigm is that oxygen consumers ‘out-compete’ nitrate consumers, for example. It has not been demonstrated that competition is involved with the structure of geochemical profiles or bacterial communities. While there is a clear trend in declining bacterial numbers with depth in the sediments, the association of bacterial turnover rates and geochemical zonation has not been explicitly shown.

A recent discovery also shows how the ‘energy cascade’ model is subject to exceptions. Cable bacteria have been shown to shuttle electrons between zones of sulfide abundance to zones of oxygen. This typically occurs in sediments over a vertical span of several centimeters (although it is not limited to the vertical orientation). This electron shuttle allows reduction of dissolved oxygen in near-surface sediments (Fig. 2). Typically, in high sulfide sediments (those undergoing rapid rates of sulfate reduction) the sulfide can diffuse until it reaches the zone of oxygen diffusing downward. But cable bacterial will bridge the sulfide-rich zone with the oxygen-plentiful zone thereby leaving a gap in the sediments where there is the absence of both oxygen and sulfide. Further, this reaction drives low pH in sulfidic pore waters and high pH near the sediment–water interface. The electron shuttling is thus a microbial mechanism that actually geo-engineers the sediment column.

Chemical Profiles in Sediments (Layered Microbial Communities)

What Is a Layered Microbial Community?

Perhaps the key indicator of an active sedimentary environment is the presence of distinct layers like those described earlier – geochemists call these chemical profiles, while geobiologists prefer to call them LMCs, or layered microbial communities. It is a semantic issue on one hand, and an important intellectual issue on the other. What is measured is pore water chemistry, and the chemical gradients are clearly seen – what is responsible for them is the activity of the resident microbes, feasting on the energy available at these interfaces, and providing the chemical catalysis for their very existence. That is, dead or sterile sediments have chemical profiles that are dictated by diffusion between end-member boundary conditions. Sediments with life often show chemical gradients that overrule diffusion as life will involve consumption or production at rates greater than diffusion, and by these activities, modify the diffusive profiles. The interplay between metabolic activity and the physics of the sedimentary environment leads to the establishment of metabolic layers, and these layers can then be used to establish the processes that lead to their establishment. The definition of a metabolic layer does not preclude any other geochemical reaction from occurring within that layer given the right circumstances – it is simply defining the predominant geochemical activity for the given environmental setting.

The chemical and biological consequences of the physical nature of sediments have to do with the solubility and movement of key nutrients through this diffusion-limited environment. Perhaps the key nutrient is oxygen, the solubility of which ranges from about 200–400 $\mu mol\ l^{-1}$ depending on temperature and salinity. Thus, one usually sees oxygen depletion in sedimentary systems, depletion that can occur within a millimeter or less of the sediment–water interface (in eutrophic (highly productive) lakes or marine sediments), to many meters in deep-sea sediments underlying the oligotrophic (minimally productive) ocean gyres. Oxygen limitation, of course, leads to the use of other electron acceptors, including nitrate, metal oxides, sulfate, and finally CO_2 . Each of these electron acceptors is used in its thermodynamic ‘order’, and its removal (or the appearance of its reduced product) can be used to characterize the microbial activity of the sediment system, as shown in Fig. 2.

The bottom line in terms of defining this environment is that the physical and geochemical conditions set the boundaries for the system; these boundaries define to some degree the chemical and biological consequences on the environment – the processes that

Fig. 2 Diagrammatic view of the cable bacteria. These bacteria, many of which appear to be affiliated with the genus *Desulfobulbaceae* in the delta Proteobacteria, form conductive multicellular filaments that allow bacteria deep in the suboxic zone to oxidize sulfide using oxygen from millimeters or even centimeters above for a review and perspective.

will occur can be predicted with some certainty – thus, the biological consequences can be predicted in terms of process. Prediction in terms of species is much less certain: For some of the processes, like oxygen depletion and nitrate reduction, many taxonomic groups are capable of the catalysis, while for others, like sulfate and CO₂ reduction, the taxa that can be expected are much more well defined (Fig. 3).

The Rates of Sediment/Solute Transport Processes

The microbial community associated with sediment solid grains is likely dependent on the movement of solutes to bring various nutrients and energy-yielding chemicals to their habitat. However, it is possible that the sediment grain to which they attach is replete with all the necessary food items. Solid grains including C_{org}, N_{org}, P_{org}, P_{inorg}, and various trace metals are commonly found adsorbed to these and other particles. The oxidants manganese oxide and iron oxide are solids themselves, and are excellent scavengers of trace metals, as well as being found associated with other solid particles. Thus, the sediment grain itself can provide all of life's essential nutrients and the ultimate source of these solid nutrients is the sedimenting particle. As energy-yielding reactions occur, for example, manganese and iron oxide reduction, some of the solid particles (e.g., manganese and iron oxides) can be solubilized, leading to the release of trace metals and other adsorbed nutrients. Such reactions can lead to movement within sediments of layers of metal oxides and the nutrients with which they are associated. Chemical thermodynamic theory predicts that the most easily reduced oxides will be utilized and depleted first, followed by other more crystalline and less reactive oxides. Thus, manganese oxides, which are very easily reduced, will almost always be reduced (solubilized) prior to iron oxides in sedimentary environments, leading to a separation of these two metals in space.

Because sediments represent a record of time, the oldest sediments are deeper within the column than shallower sediments, and because metal oxide depletion occurs close to the sediment–water interface, as particles are buried, the abundance of easily reducible iron or manganese oxides declines. Reduced manganese and iron are soluble and will diffuse away from regions of high concentration. The consequence of this process is that manganese and iron oxides get diagenetically recycled or regenerated when these solutes come in contact with molecular oxygen or nitrate. Alternatively, the reduced manganese and iron may be sequestered as minerals. The reoxidation generally occurs near the sediment–water interface. Thus, a cycle of manganese and iron reduction and oxidation is very common in sediments overlain by water containing oxygen or nitrate.

Fig. 3 Comparison of freshwater and marine pore water profiles from Lake Michigan (Nealon Laboratory) and Santa Barbara Basin (Berelson Laboratory). Of particular note is the lack of oxygen in Santa Barbara Basin sediments, the rapid removal of Fe(II) and Mn(II) in these sediments and the high concentration of ammonia within these marine sediments. The production of ammonia in Lake Michigan sediments is linked to denitrification, sulfate reduction, and metal reduction.

The reoxidation of reduced metals generates a surplus of solid-phase oxidants near the sediment–water interface. However, the process of bioturbation, the physical mixing of sediments by the activity of macrofauna, will carry oxidized Fe and Mn particles downward into the deeper sediment column where solute oxidants are absent. Hence, not only are Fe and Mn recycled and renewed when they become oxidized from the soluble reduced form, but they are also injected back into zones that are free of oxidants by sediment mixing. In sediments subjected to bioturbation, there will always be a race between microbes adapting to their particular redox environment before mixing carries them into a new and different redox zone.

Microbial environments also change within sediment habitats because there is a slow transport of pore water due to the compression of sediments as burial progresses. Upon initial settling, sediments are relatively uncompacted – the porosity can approach 0.95 or greater. As sediments become buried, compaction of the grains reduces the porosity. By 10 cm the porosity may be reduced by 10%, by 10 m the porosity is often reduced by 25%–40%. This effectively creates an upward flow of pore water, relative to the compacting sediment (the water is incompressible; the grains settle and compact within this medium, giving the mathematical impression of advective ‘flow’ toward the sediment–water interface). This advective process, termed pore water advection, will juxtapose pore water microbial communities with sediments other than those with which they were originally associated. In shallow coastal regions and some lakes, the rate of sediment accumulation is fast and the upward advection of pore water can be on the order of centimeter per year. However, in most of the ocean this rate is very slow, much lesser than a millimeter per year.

Because sediment pore water is generally not subject to turbulent mixing, the most ubiquitous transport mechanism for solutes moving through sediments is molecular diffusion. In the absence of any chemical reaction, diffusion would homogenize the concentration of all solutes throughout the sediment column. And in the vast majority of ocean sediments that are absent of bioirrigation or other mass transport processes, diffusion limits the rate at which solutes can move through pore fluids. An added complication in a pore water–sediment environment is that diffusion cannot take a straight path between high and low concentration. Sediment grains effectively block the most direct diffusive path length; hence, the term tortuosity describes how far from linear the path length has become.

The fact that virtually all sediment pore water solute profiles of the biologically relevant chemicals show curvature, maxima, and minima and approach zero is evidence that there are reactions occurring within the sediments. As diffusion will generate a linear

gradient between two fixed boundary conditions, the curvature in a solute profile is easily transformed into an understanding and quantification of reaction rates. The production or consumption of a chemical between two sediment horizons is defined by the flux across each boundary. If more solute is entering the sediment zone (between the two defined horizons) than is leaving the zone, there is net consumption occurring between these horizons. If more solute is leaving a sediment zone than is entering, there is net production occurring within that zone. The rate at which a solute will pass through a sediment horizon (a plane) via diffusion is defined by Fick's first law:

$$J = -\frac{dC}{dz} D \phi$$

where J is the flux (moles $\text{cm}^{-2} \text{s}^{-1}$), C the concentration in pore water, z the depth in sediment, D the compound's molecular diffusivity (corrected for the tortuosity and considered a physical constant for a given ion, given temperature and salinity), and ϕ the sediment porosity. The difference in flux between two sediment horizons defines the reaction rate. Production or consumption is defined as

$$R = \frac{J_1 - J_2}{z}$$

where R is production or consumption (moles $\text{cm}^{-3} \text{s}^{-1}$), J the flux across horizon 1 or 2, and z the distance between horizons 1 and 2.

The ability to translate geochemical gradients into an understanding of fluxes and reaction rates (production and consumption) is extremely important to understanding microbial activity in sediments. A rate measurement made from diffusive flux calculations at two sedimentary horizons will, of course, only be as good as the quality of the gradient data and the assumption that diffusion is the major transport mechanism. Yet these types of data and the diffusive assumption are remarkably robust, and form the basis for much of our thinking about sedimentary dynamics.

It can be informative to compare bulk sediment reaction rate calculations, derived and used by geochemists, to microbial respiration rates as determined by microbiologists. There are numerous estimates of the rates of oxygen consumption in sediments, but to our knowledge, there are no published microbial oxygen respiration rates normalized to a per cell basis. To this end, our own laboratories have made some bacterial oxygen consumption measurements and found that within a factor of 3, microbes during growth phase can consume oxygen at a rate of $50 \times 10^{-10} \text{ nmol CFU}^{-1} \text{s}^{-1}$. Given this rate of oxygen consumption per cell and applying a rate of $0.05 \text{ nmol cm}^{-3} \text{s}^{-1}$ for bulk sediment oxygen consumption (a high rate indicative of eutrophic coastal environments) suggest that $1 \times 10^7 \text{ cells cm}^{-3}$ in growth phase could account for the measured oxygen consumption. This might represent 1%–10% of the cells living in a sediment community, or imply that few, if any, of the cells are in the so-called growth phase that we so often study in the laboratory.

There are also many published values for sulfate reduction rates (SRRs) in sediments, generally established using a tracer spike of radiolabeled ^{35}S , applied to recently collected bulk sediments, but in this case, in opposition to the situation with oxygen, there are many published estimates of SRRs per cell, generally measured on pure cultures in the laboratory. The range of SRR per cell is very broad, as are rates measured in the field, but given published values of SRR within bulk sediments, and a range of 3 orders of magnitude in cellular SRRs, it is possible that sulfate-reducing bacteria (SRB) make up a substantial fraction (>10%) of the total sediment inventory.

The two abovementioned examples demonstrate that the connection between cellular activity and bulk sediment activity is not well understood. One outstanding question is how many sedimentary microbes are undergoing exponential growth, and another is whether there are a few superconsumers or if all sedimentary microbes are tuned to respire within a certain range. It is certainly true that sedimentary microbial systems dominated by C_{org} respiration are much more complex than pure cultures examined during optimal growth conditions.

Can Microbial Populations be Predicted From Chemical Layers?

One of the key questions that arises from the study of sedimentary environments is that of whether or not it is possible to predict the nature of the microbial populations by the profiles that are present. We propose that it is to some extent possible to predict the general nature of the reactions that must have taken place to account for the observed profiles. However, that is probably as far as it goes. There is a tremendous redundancy in nearly every process – a redundancy that precludes the specification of which phylotypes should be expected to be present. Thus, historically, one has had to settle with knowing that oxygen utilizers, denitrifiers, iron and manganese reducers, and so on must be present. Add to this the fact that the taxonomic diversity of microbial sediment communities is far greater than the few of the sediment organisms that have been cultivated, and the situation has looked impossibly complex for decades.

For example, as the geochemists would identify the 'zone of manganese reduction' by a profile of manganese as shown in Fig. 2, microbiologists would call this the zone of manganese reducer activity. However, there are literally hundreds of different microbial species capable of manganese reduction, thus relegating one to specifying processes rather than names of species, or even genera.

The other part of the predictive process is that most of the processes being studied are in fact cyclical. The oxygen diffusing down into the sediments acts not only as the electron acceptor for heterotrophic metabolism, but as the oxidant of many

inorganics, regenerating them for further oxidative activity in the zones of reduction. Thus, near every reductive interface, as described by the geochemists, is an oxidative one, in which the electron acceptors are regenerated, almost always via the microbial activity(ies). As with the reductive activities discussed earlier, these activities can be specified, but the microbes responsible for them have been very difficult to identify and have traditionally only be designated by metabolic group.

To this end, the rapidly moving fields of molecular taxonomy, genomics, metagenomics, and metatranscriptomics have made it possible to identify and quantify the members of sediment microbial populations (ref), identify the gene content of different sediments, assemble the genomes of the microbes that are present, and even pinpoint which genes are being induced by which organisms. While it is not yet possible for one to link microbes and their activities to the geochemical patterns seen in sediments, the future looks bright in terms of teasing apart the microbial interactions that are occurring within this ecosystem using a combination of metagenomics, genome assembly and analysis, and metatranscriptomics coupled with stable isotope probing and metabolomics approaches.

Complications to the usual view of LMCs have been generated with the discovery of the so-called cable bacteria by the laboratory of Lars-Peter Nielsen and colleagues. These bacteria, now known in marine sediments around the world, form multicellular filaments that allow the transfer of electrons from hydrogen sulfide, across several redox zones to the oxygen zone, sometimes far away from the source of reductant, as illustrated in Fig. 2. They also represent a phenomenon that is now well described operationally, but which is not yet understood mechanistically.

For the microbial ecologist, then, the sedimentary environment remains a great challenge in terms of understanding the diversity and interactions that occur as one proceeds downward through the LMCs.

Sediments as a driving force for discoveries in microbiology

During the past decades, it has become apparent that careful geochemical analysis of sediments reveals microbiological processes that must be occurring to explain the observed profiles. One of the most distinguishing features of life is its ability to catalyze reactions that, while thermodynamically favorable, are kinetically constrained due to large activation energies. Indeed is the invention of specific protein catalysts (enzymes) is key to the success of life, allowing low-temperature conversion of many different energy sources. To this end, as noted below, it is notable that some major discoveries in microbial metabolism were discovered in attempts to explain sedimentary data in which the rates of geochemical processes were far too rapid to be explained by chemistry alone.

Anaerobic methane oxidation

In the late 1970s and early 1980s geochemical data from two different laboratories noted the disappearance of methane at depth in marine sediments, far below the oxic/anoxic interface (Goldberg & Barnes; Rheebrugh), a process that at the time was deemed impossible by microbiologists. The geochemical data, however, were convincing, and after considerable searching, two laboratories reported the existence of microbial enrichments that catalyzed anaerobic methane oxidation (Delong & Orphan; Jorgensen & Boetius), leading eventually to the identification of the ANME group of Archaea capable of catalyzing anaerobic oxidation of methane in concert (symbiosis) with sulfate reducing bacteria.

Manganese reduction/extracellular electron transport

In the early 1980s geochemical flux data from Oneida Lake in New York revealed rates of manganese oxide reduction that were orders of magnitude too fast to be explained by the chemistry of the lake sediments (Moore). A similar situation was reported for iron flux from sediment incubations from the Potomac river (Lovley). For both iron and manganese oxides, reduction by direct electron transfer was deemed to be impossible, as the metal oxides are insoluble and thus not available for direct reduction. As with the anaerobic methane oxidation, however, the process was revealed by the geochemical data, and enrichment cultures for iron and manganese reducers revealed two different groups of metal reducers, Shewanell (Myers and Nealson, 1988) and Geobacter (Lovley and Phillips, 1988), both of which proved to be capable of transporting electrons to solid substrates outside the cell via a process now termed extracellular electron transport, or EET.

In both of the examples noted above, considerable variation on the original “theme” has been seen, and major changes in the view of microbial physiology have occurred in the search for answers to geochemical anomalies.

Complications Introduced by Activities of the Macrofauna

Sediments that are mixed by macrofaunal activities (bioturbation) show complexities in microbial distribution due to the introduction of oxygen (and other oxidants) at depth due to burrowing, pumping of water, and other activities of multicellular macrofauna of a variety of types (Fig. 1). Despite these activities, however, which tend to mix the upper surface of the sediments, one sees that bacteria distribute themselves along geochemical gradients and, in fact, are often responsible for the maintenance of these gradients although sometimes pore water chemistry and microbial community structure are uncoupled by this process. Sediments that do not undergo physical mixing provide excellent systems for the calibration of bacterial community activity, gradient formation, and community evolution: Mixed sediments provide sites for understanding the same processes in a much more complex setting of 3-dimensional diffusion gradients, perhaps more reminiscent of soil environments.

Intersection of Chemical Gradients

A fascinating feature of sediment communities relates to the places in which chemical gradients of different types intersect with one another, such as can be seen the sulfate/methane horizon in deep-sea cores. At such interfaces abundant microbes are seen, and the process of anaerobic methane oxidation, which occurs seldom if at all elsewhere, is abundant. The advantage of living near a redox boundary is that the energy-yielding reaction space increases: For example, oxygen utilization in the respiration of C_{org} requires a microbial community capable of breaking C_{org} into oxidizable-sized compounds and it requires that the respiring microbes 'find' both the oxidizable compound and the oxygen simultaneously. The presence of oxygen in contact with ammonia, diffusing up from deeper in the sediment column, provides a fixed location where both energy-yielding compounds coexist. In fact, the constancy of geochemical gradients and redox boundaries within the sediment column is evidence that sedimentary microbes adapt to and will aid in the perpetuation of these gradients and boundaries.

Sometimes the net free energy yield of a coupled set of geochemical reactions is sufficient to support a sedimentary microbial community even when some of the 'players' are working in a free energy deficit. An example of this is where sulfate is used in the oxidation of methane, a process known to be catalyzed by a consortium of archaeal methanotrophs and SRB. It has been determined that while the SRB capture significant energy from this coupled reaction, using H_2 as an intermediate, there must be something 'in it' for the archaea for their role in this coupled reaction costs them energy.

The further one looks into sedimentary bacterial activities, the more one sees that a simple thermodynamic explanation (i.e., the free energy paradigm) is a rule that is commonly broken. Under eutrophic and low oxygen water columns lie sediments containing little or no oxygen. In these sediments live bacteria that can sequester nitrate from the overlying water column and transport that nitrate within the sediments to zones where sulfide is present in high quantities. Under diffusive conditions, nitrate would not penetrate to the depth of high sulfide, yet these bacteria, for example, *Beggiatoa* and *Thioploca*, are capable of bypassing the diffusive zone and injecting nitrate into sediments rich in sulfide, thereby oxidizing the sulfide to S^0 or SO_4^{2-} . An unsolved enigma is that the greater free energy yield would be obtained if nitrate were to react with C_{org} compounds. Sedimentary bacteria find ways to utilize unusual combinations of reduced and oxidized compounds, not only those in association with free solutes but also those in the solid phase. This is, like the cable bacteria, yet another example of exceptions to the LMC rule.

Recent findings have revealed a surprisingly high diversity in marine sediments of microbes capable of using solid-state electron donors, including poised electrodes as energy sources (see references to Rowe and Lam), further complicating the energetic situation in sediments, especially those that may be lacking in abundant organic carbon (see below).

Organic-Poor Sedimentary Environments

Recent studies of deep-sea sediments underlying low productivity oceanic zones have revealed that a major part of the deep sea (perhaps 20% or more) consists of sediments that are so organic poor that the numbers of microbes are far less than those usually encountered in near-shore and productive environments. For example, Steve D'Hondt, Bo Jørgensen, and their colleagues, in studies of sediments in the South Pacific gyre area, have found surface sediments that typically harbor only 10^3 – 10^5 bacteria per gram of sediment – orders of magnitude below those found in other more nutrient-rich horizons. Predictably, the chemical gradients typical of more active zones are absent here. Life becomes 'cryptic' in terms of using geochemical profiles to define it. The nature of the microbes in such environments is curious – they appear to be alive, but nondividing or extremely slowly dividing, with estimates of doubling times extending to thousands of years.

Subsurface Sedimentary Microbiology

In a situation similar to that seen in nutrient-poor sediments, the deep subsurface of ocean sediments appears to harbor a low-density (10^5 per gram) population that is dividing at very low rates (again, perhaps thousands of years). This so-called starving majority as it has been called by Bo Jørgensen constitutes one of the current great mysteries in microbial ecology, and it is tempting to speculate that it may be similar to environments of early Earth, when C_{org} may have been much less abundant, and organisms might have utilized mechanisms for survival not often needed on the nutrient and energy-rich surface of our planet. The radiolytic dissociation of water and production of hydrogen gas may be an energy source to these nutrient poor environments, as may be the reduced iron and sulfur-containing solid minerals.

Paleontological Properties of Sediments: The Rock Record

As noted earlier, diagenesis is the process of sediment alteration, a process that begins as soon as the sedimentary material arrives, and continues as long as energy is flowing through the system. Superimposed on this are the paleontological consequences of sedimentation. As diagenesis occurs, a number of biosignatures can be deposited as records left to be examined in ancient sediments – records of early metabolism, even in the absence of living biomass, or even cell structures. Biosignatures can consist of molecules indicative of certain taxa and the processes they catalyze (i.e., markers indicative of photosynthetic activity, particularly of oxygenic photosynthesis), as well as stable isotopes of carbon, sulfur, and/or nitrogen that can be fractionated by biological

systems. Such molecular or isotopic fossils are often the only records available in the ancient sediments, and even these are often altered beyond recognition by diagenesis and metamorphism (cooking and alteration!) of the sediments. However, it is these ancient sediments and their geobiological records that provide hints as to the earliest metabolism(s) on Earth, and even to the first detectable signs of life on our planet.

Sediments in Shallow Water, and the Impact of Light

Almost everything discussed in this article has dealt with the sedimentary environment in the deeper and dark zones of oceans and lakes. Of course, along the continental margin, and in many lakes, sunlight can penetrate the overlying water, adding new complexity to the sedimentary environment. Now the environment becomes even more distinctly layered, often with oxygen-producing cyanobacteria at the surface, and other layers of anoxygenic photosynthetic bacteria below. The oxygen penetration depth can change dramatically between day and night, with oxygen production by the cyanobacteria during the day often pushing the oxic zone to several centimeters, and oxygen consumption by the heterotrophs leading to anoxia, even at the surface at night. This being said, however, the general features of the environment still apply: It is a permanently wet, diffusion-controlled niche that is strongly impacted by physical (porosity, tortuosity, etc.) and chemical (salinity, anion content, etc.) factors.

Conclusions

In closing, it is appropriate to remind ourselves of the general properties of the sedimentary niche, which is perhaps the largest single niche available to life on the planet.

- (1) Sediments are not soils – they accumulate biomass by sedimentation from above, and are constantly water saturated.
- (2) Sediments are physically stabilized, and therefore solute distributions are primarily controlled by diffusion – nutrients must diffuse from above (or sometimes below), and this diffusion controls the overall character of the niche.
- (3) Sediments can (and often do) have zones of bioturbation, a type of mixing imposed by eukaryotic multicelled organisms that pump water and nutrients into the sediments, as well as physically mixing the environment.
- (4) Sediments typically become anoxic due to respiration of the microbial population removing the oxygen at a rate faster than it can be supplied by diffusion, thus leading to widespread anoxic sediment distribution.
- (5) Other oxidants (nitrate, manganese oxides, iron oxides, sulfate, and CO_2) are then used up via respiration, leading to chemical layering of sediments, processes that result in LMC formation.
- (6) Pore water analyses reveal the existence and nature of the LMCs in sediments, and allow one to specify to some degree the nature of the processes occurring in a given sedimentary habitat.
- (7) Sediments in the photic zone take on new properties due to the daily cycles of photosynthesis and oxygen consumption, and are further complicated by the input of organic matter directly to the environment by photosynthesis. However, they are still permanently wet, diffusion-controlled systems, subject to the same rules as other sediments.
- (8) Sediments are in general excellent habitats for prokaryotes, with 10^9 per gram or more cells being common. The sedimentary niche may harbor up to 50% of the biomass on our planet, and interact strongly with the biogeochemical cycles of nearly every major biologically active element.

Glossary

Cache Sensor domain found in calcium channel and chemotaxis proteins.

EAL domain Conserved protein domain, usually with *c*-di-GMP-specific phosphodiesterase activity, named after its conserved Glu-Ala-Leu sequence motif.

HAMP domain Conserved cytoplasmic linker domain, named after histidine kinases, adenylate cyclases, methyl carrier proteins and protein phosphatases, where it was originally described.

HD-GYP domain Conserved protein domain, usually with *c*-di-GMP-specific phosphodiesterase activity, named after its two conserved sequence motifs, His-Asp and Gly-Tyr-Phe.

GAF domain Conserved ligand-binding protein domain, named after cGMP phosphodiesterases, adenylate cyclases, and FhlA proteins, where it was originally described.

GGDEF domain Conserved protein domain, usually with diguanylate cyclase (*c*-di-GMP synthetase) activity, named after its conserved Gly-Gly-Asp/Glu-Glu-Phe sequence motif.

MASE Membrane-associated sensor domain.

PAS domain Conserved ligand-binding protein domain, named after period circadian protein (Per), Aryl hydrocarbon receptor nuclear translocator (ARNT), and single-minded protein (Sim) proteins, where it was originally described.

Phosphorylation Transfer of the phosphoryl group $-\text{PO}_3^{2-}$ (the phosphate group $-\text{O}-\text{PO}_3^{2-}$ without an oxygen atom), for example, from ATP to various acceptors.

Protein domain A discrete structural unit of proteins that can be found in different contexts. Most domains range in size from 50 to 300 amino acid residues.

Protein motif A group of amino acid residues, conserved among several different proteins.

REC domain Receiver domain, a conserved protein domain that is similar to the CheY chemotaxis protein and contains a conserved Asp residue that can be reversibly phosphorylated by histidine kinases or artificial phosphoryl donors.

General Principles of Signal Transduction

The ability to sense changes in the environment and respond to them is a key property of all living cells. In principle, the level of a cellular metabolite could be regulated by simple feedback mechanism with a single transcriptional regulator. For example, a simple system consisting of a cellobiose-binding transcriptional regulator and a cellobiose-degrading enzyme would be sufficient for controlling the level of cellobiose in the cell. Increased levels of cellobiose would shift a larger proportion of the transcriptional regulator into the active (DNA-binding) form, which would lead to increased expression of the cellobiose-degrading enzyme that would eventually lead to the decrease in cellobiose level. Decreased levels of cellobiose would cause dissociation of the sugar from the transcriptional regulator, gradual decrease in the expression of cellobiose-degrading enzyme and, as a result, stabilization of the cellobiose level.

Such simple schemes allow the cell to respond to the changing levels of a cellular metabolite and are used—with modifications—by a variety of regulatory systems. However, this kind of regulation is not highly sophisticated and will not allow coordinated regulation of complex metabolic pathways. Rather than measure the levels of nutrients in the cytoplasm, it is strategically more efficient for the cell to monitor the environmental levels of these nutrients. That would make it possible, even at relatively low levels of certain nutrients outside the cell, to induce the respective transport systems and import these nutrients. This is exactly the strategy utilized by many bacteria. For example, uptake of glucose-6-phosphate and several other sugar phosphates by *Escherichia coli* is induced by micromolar levels of extracellular glucose-6-phosphate, which are 1000 times less than the concentration of this glycolytic intermediate in the cell. It also makes sense to detect antibiotics and other toxins in the external milieu before such compounds damage the cell. The question then becomes how to detect an extracellular signal and transmit the information into the cell. Summing up, bacterial signal transduction systems, as opposed to feedback mechanisms, are usually utilized to:

- Detect extracellular signals of a chemical or physical nature, particularly weak ones
- Detect antibiotics, toxins, and other hazardous substances before they irreversibly damage the cell

This article is an update of M.Y. Galperin, Sensory Transduction in Bacteria, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 447–463.

- Regulate complex cellular processes. The complexity of the cellular organization calls for highly coordinated response(s) to environmental challenges, making it necessary for the signal transduction machinery to constantly monitor a variety of extracellular conditions (pH, osmotic stress, redox level, nutrient levels, presence of neighbors), and organize defined, yet confined, hierarchical responses at appropriate cellular locations.

Detection of environmental signals is usually carried out by transmembrane proteins that are composed of an extra-cytoplasmic (periplasmic or extracellular) sensory domain, usually located at the N-terminus of the protein, one or several transmembrane segments, and a cytoplasmic effector domain (Fig. 1). The cytoplasmic domain typically (1) occupies the C-terminal part of the protein, (2) serves as a signal-transducing module, and (3) is enzymatically active as a dimer (or multimer). It is believed that signal reception (i.e., ligand binding) by the extracellular domain causes a conformational change that favors dimerization of the effector domains enabling their enzymatic activity. The mechanisms of the propagation of the signal across the membrane are still not yet fully elucidated and subject of research and debate.

The environmental signals monitored by the bacterial cell vary in nature, intensity and over time and may include changes in temperature, pressure, light intensity, pH, salt concentration, changes in the levels of nutrients in the surrounding medium, levels of oxygen and reactive oxygen species, levels of other terminal electron acceptors, CO₂, CO, NO, and other dissolved gases, proximity of other cells, and possibly many other parameters. Accordingly, cellular responses can occur at several levels, such as individual genes and operons, the whole-cell level (chemotaxis, phototaxis, sporulation), and the level of multicellular communication (e.g., biofilm formation). The regulation of gene expression can occur at the transcriptional, posttranscriptional (e.g., changes in mRNA stability), translational, and posttranslational (e.g., modulation of enzyme activity) levels. For this reason, the signal transduction machineries comprise mechanisms of communication not just between the sensory and the response modules, but also between different and independent modules.

Types of Bacterial Receptors and Signaling Pathways

Public Resources on Signal Transduction

Our current knowledge of signal transduction comes from a combination of genetic, physiological, and biochemical studies, primarily on model organisms such as *E. coli*, *Bacillus subtilis*, *Caulobacter crescentus*, *Myxococcus xanthus*, *Pseudomonas aeruginosa*, *Synechocystis* sp., and *Halobacterium halobium*, from bioinformatic analyses of signal transduction proteins, and from structural characterization of some of these proteins. Comparative analysis of protein sequences played a key role in the identification of the receiver (phosphoacceptor) domain in several different response regulators, which paved the way to the discovery of two-component signal transduction. In the past several years, availability of complete genome sequences led to a dramatic expansion of the list of organisms that could be used for comparing signal transduction proteins. Even more importantly, analysis of genome sequences allowed an accounting of all signal transduction proteins encoded in any given genome. This analysis revealed the presence of previously unknown receptor proteins even in such favorite model organisms as *E. coli* and *B. subtilis*. It also showed that the complexity of signal transduction systems encoded in these two organisms is rather modest, compared with the signaling repertoire of, for example, *P. aeruginosa* or *Synechocystis* sp., not to mention the enormous expansion of signaling genes in the genomes of *M. xanthus* or *Streptomyces* spp.

The diversity and complexity of the bacterial signal transduction machinery make a systematic description of its components in any given organism a difficult task (for *E. coli*, such a description is provided at the end of this article). Furthermore, it is hard—if at all possible—to make generalizations for the signaling systems across the entire bacterial world. Most of the current work is devoted to characterizing and comparing individual sensory pathways in selected bacteria and lacks a “grand view.” This has led to creation of public databases that attempt to collect information on the whole spectrum of signal transduction systems in various organisms. Several such databases are freely available online (Table 1). Unfortunately, several popular databases have been recently discontinued, and some others have not been updated for a long time. Nevertheless, these web sites still offer helpful insight into the organization of the signal transduction machinery in certain bacteria.

The microbial signal transduction (MiST) database, which used to offer information on the signal transduction proteins from all completely sequenced bacterial and archaeal genomes, identified by their domain architecture, is currently unavailable but is expected to be back online in the near future. The P2CS database lists predicted two-component signal transduction proteins from all completely sequenced bacterial and archaeal genomes. It also provides manually curated annotations of the major classes of response regulators. Kyoto Encyclopedia of Genes and Genomes (KEGG) is a comprehensive genomic database on all completely sequenced bacterial, archaeal, and eukaryal genomes. One of its sections provides a graphical representation of all bacterial two-component systems. Kinases in Genomes (KinG) database provides a comprehensive listing of Ser/Thr/Tyr kinases and related proteins encoded in various bacterial, archaeal, and eukaryal genomes. Finally, Signaling Protein Census and Response Regulator Census, two web sites maintained by one of the authors, provide counts of each class of signal transduction protein and response regulator in complete genomes from more than 500 bacterial and archaeal species.

In addition, signal transduction pathways for individual model organisms are often well covered in organism-specific databases, such as EcoCyc (<https://ecocyc.org/>, part of the vast BioCyc database collection) for *E. coli*, SubtiWiki (<http://subtiwiki.uni-goettingen.de/>) for *B. subtilis*, *Pseudomonas* Genome Database (<http://www.pseudomonas.com/>) for various pseudomonads, and CauloBrowser (<http://www.caulobrowser.org>) for *C. crescentus*. It is worth checking these databases before undertaking any genome analysis project: there is a good chance that these databases already contain all the answers.

Fig. 1 Domain architectures of some bacterial receptors. (1) *Escherichia coli* citrate-sensing histidine kinase DpiB (UniProt accession number [P77510](https://www.ebi.ac.uk/interpro/protein/P77510), InterPro entry <https://www.ebi.ac.uk/interpro/protein/P77510>). (2) *E. coli* turgor-sensing histidine kinase KdpD (P21865). (3) *E. coli* chemotaxis histidine kinase CheA (P07363). (4) *E. coli* serine chemotaxis receptor Tsr (P02942). (5) *E. coli* redox chemotaxis receptor Aer (P50466). (6) *E. coli* PTS system glucose-specific EIICB component PtsG (P69786). (7) *Anabaena variabilis* serine/threonine protein kinase with Chase2 sensor domain (Q3M3S5). (8) *Leptospira interrogans* serine phosphatase RsbU, regulator of sigma subunit (Q8F087). (9) *Pseudomonas aeruginosa* adenylate cyclase CyaB (Q9HZ23). (10) *E. coli* diguanylate cyclase AdrA (P0AAP1). (11) *E. coli* c-di-GMP phosphodiesterase Dos (P76129). (12) *E. coli* c-di-GMP phosphodiesterase BluF (P75990). Domain names are as [Tables 3 and 4](#); striped boxes indicate individual transmembrane segments; dotted shapes indicate integral membrane domains, containing multiple transmembrane segments. Pfam entries for other domains are as follows: USP, PF00582; CheW, PF01584; TarH, PF02203. Domain sizes are not necessarily drawn to scale.

Signal Transduction Pathways

Historically, experimental studies initially focused on two classes of membrane-bound receptor proteins, sensory histidine kinases and methyl-accepting chemotaxis proteins (MCPs). Subsequent analyses of microbial genomes, as well as experimental studies, revealed several additional classes of bacterial receptors, which include Ser/Thr/Tyr protein kinases and protein phosphatases, membrane components of the sugar:phosphotransferase system (PTS), adenylate cyclases, diguanylate cyclases and c-di-GMP-specific phosphodiesterases, and diadenylate cyclases ([Table 2](#)). It must be noted that, in addition to transmembrane sensors, there exist cytoplasmic versions of these receptors that appear to sense intracellular cues but use the same signal transduction machinery to propagate the signal and trigger the cellular response. Such cytoplasmic forms have been found for all kinds of receptors listed in [Table 2](#) except for the membrane components of the PTS.

Table 2 Principal classes of bacterial and archaeal receptors

Receptor type	Regulated functions	Signaling mechanism	Phylogenetic distribution
Histidine kinase	Regulation of transcription, other signaling systems	Phosphorylation of the receiver domain in various proteins	Bacteria, archaea
Methyl-accepting chemotaxis protein	Chemotaxis	Interaction with chemotaxis-specific histidine kinase CheA	Bacteria, archaea
Ser/Thr/Tyr protein kinase	Regulation of transcription, enzyme activity	Phosphorylation of Ser, Thr, or Tyr residues in target proteins	Bacteria, archaea
Ser/Thr/Tyr protein phosphatase	Same as above	Dephosphorylation of Ser, Thr, or Tyr residues in protein kinases or other proteins	Bacteria, archaea
Membrane components of the sugar: phosphotransferase system (PTS)	Sugar transport, chemotaxis	Binding of EIIA ^{Glc} and/or EI to chemotaxis proteins, adenylate cyclase, membrane transporters	Bacteria
Adenylate cyclase	Global regulation of transcription	Synthesis of cAMP	Bacteria
Diguanylate cyclase	Regulation of motility, cell division, protein and polysaccharide secretion	Synthesis of c-di-GMP	Bacteria
c-di-GMP-specific phosphodiesterase	Same as above	Hydrolysis of c-di-GMP	Bacteria
Diadenylate cyclase	Sensing of DNA integrity, cell wall stress	Synthesis of c-di-GMP	Bacteria, archaea

The signaling pathways utilized by various bacterial receptors are shown on Fig. 2. Signaling by histidine kinases is usually referred to as two-component signal transduction, as it includes phosphoryl transfer between two separate proteins, a histidine kinase and a response regulator. Two-component signal transduction pathways are extremely diverse but always include the following common steps: (1) ATP-dependent phosphorylation of a conserved His residue in the kinase; (2) transfer of the phosphoryl residue to a conserved Asp residue in the receiver (REC) domain of the response regulator; (3) conformational change in the response regulator that alters its interaction with the target(s). The majority of response regulators serve as transcriptional regulators and bind to the chromosomal DNA, but there are response regulators with alternative targets (see below).

Chemotaxis signaling, which starts from MCPs, is a special case of two-component signal transduction that involves a specialized histidine kinase CheA, which directly interacts with MCPs, and a separate response regulator CheY that represents a stand-alone REC domain without output domains. Regulation of flagellar motility is based on the interaction of the phosphorylated form of CheY (CheY~P) with the FliM protein at the base of the flagellum, which affects FliM, FliN, and FliG proteins and changes the direction

Fig. 2 Signal transduction pathways of the principal classes of bacterial receptors. (1) Transcriptional regulation by two-component signal transduction systems usually includes a sensor histidine kinase and response regulator that consists of the phosphoryl-accepting receiver (REC) domain and a DNA-binding helix-turn-helix (HTH) domain. (2) Signal transduction in the *Bacillus subtilis* sporulation machinery includes a histidine kinase (KinA, KinB, KinC, KinD, or KinE), response regulator (Spo0F) with a stand-alone REC domain, intermediate phosphorelay component (Spo0B) and transcriptional response regulator Spo0A that consists of REC and Spo0A-specific HTH domains. (3) Signal transduction in the chemotactic machinery starts from a sensor (methyl-accepting chemotaxis protein, MCP) that interacts with the histidine kinase CheA, which phosphorylates CheY. Phosphorylated CheY interacts with the FliM protein at the base of the flagellum and with still unknown targets in other systems. (4) In *E. coli*, signal transduction in the phosphoenolpyruvate-dependent sugar:phosphotransferase system (PTS) involves protein-protein interactions involving the nonphosphorylated forms of PTS components EI and EIIA. EIIA interacts with adenylate cyclase, glycerol kinase, maltose transporter and some other proteins, while EI can interact with the chemotaxis histidine kinase CheA. In *B. subtilis*, the nonphosphorylated form of EI interacts with one of the MCPs. (5) Signal transduction from Ser/Thr/Tyr protein kinases involves direct or indirect phosphorylation of various (mostly unknown) targets. Known targets of Ser/Thr/Tyr protein phosphorylation include metabolic (e.g., glycolytic) enzymes and transcriptional regulators. (6) Signal transduction from sensor adenylate cyclases involves interaction of the cAMP with specific cNMP-binding domains, found in the transcriptional regulator CRP and in a few other proteins. The cAMP-CRP complex binds to the chromosomal DNA and activates transcription from a variety of bacterial promoters. There are also other targets of cAMP action. (7) Signal transduction from sensor diguanylate cyclases involves interaction of c-di-GMP with proteins that contain PilZ, MshEN or other c-di-GMP-binding domains. c-di-GMP hydrolysis is catalyzed by c-di-GMP-specific phosphodiesterases, containing either EAL or HD-GYP domains. In addition, c-di-GMP serves as an allosteric regulator of its own production. Domain names are as in Tables 3 and 4. Domain architectures are simplified for clarity and domain sizes are not drawn to scale.

of flagellar rotation. In archaea, whose flagella (archaella) are unrelated to the bacterial ones, there is no FlhM homolog and Che $\sim$ P binds to the archaeal-specific adaptor CheF. In bacteria that move by type IV pili or utilize other nonflagellar means of motility, such as gliding, the targets for CheY $\sim$ P binding remain obscure but likely include specific motor proteins. Recent studies revealed that signaling components of certain MCPs reach beyond chemotaxis. For example, in *M. xanthus*, an MCP has been shown to participate in regulation of developmental gene expression, whereas in *P. aeruginosa*, methyl-accepting protein WspA turned out to be part of a chemosensory system that regulates biofilm formation.

Components of the PEP-dependent sugar:phosphotransferase system (PTS) participate in uptake of sugars, coupled with their phosphorylation, and are rarely considered to be part of a signal transduction machinery. Yet, two members of the PTS phosphorylation play key roles in signal transduction. The phosphorylation level of the PTS enzyme I (EI) directly affects the chemotaxis machinery, whereas the phosphorylation level of the enzyme IIA^{Glc} (EIIA^{Glc}) modulates the activity of certain membrane transporters and such enzymes as the adenylate cyclase, at least in *Enterobacteriaceae*.

Ser/Thr/Tyr protein kinases phosphorylate Ser, Thr, and/or Tyr residues in various cellular proteins. Analyses of cell-wide protein phosphorylation revealed a wide variety of phosphopeptides coming from numerous cellular proteins. However, only a small fraction of them appear to be true targets of regulation by Ser/Thr/Tyr protein kinases. These include transcriptional regulators (such as actinobacterial AfsR) and metabolic enzymes (e.g., phosphofructokinase). Ser/Thr/Tyr protein phosphatases reverse the effect of Ser/Thr/Tyr protein kinases by dephosphorylating these target proteins or, in some cases, the protein kinases themselves. Most of these enzymes are in the cytoplasm and only a few are membrane-bound.

Adenylate cyclases convert ATP to cyclic adenosine 3',5'-monophosphate (cAMP), a key cellular second messenger. There are several different classes of adenylate cyclases, of which only class III enzymes have been shown to function as transmembrane receptors. Cyclic AMP participates in at least two different signaling pathways, both mediated by its interaction with a specific (cNMP-binding) domain of the target proteins. In bacteria, cAMP typically binds to a cAMP receptor protein (CRP, also known as catabolite activator protein, CAP). Cyclic AMP binding triggers a conformational change in CRP that increases its affinity to regulatory DNA sequences and allows it to interact with the RNA polymerase and activate transcription from certain weak promoters. This way, activation of adenylate cyclase(s) stimulates transcription of certain genes (operons) that are poorly expressed in the absence of the cAMP-CRP complex. This regulatory mechanism is sometimes referred to as catabolite repression, although the classical catabolite repression (or glucose effect) is a sum of several independently acting mechanisms. The second pathway of cAMP-mediated signaling is an allosteric regulation of the activity of certain target proteins. In bacteria, it can be mediated by cAMP-binding to a GAF domain of multi-domain signal-transduction proteins. In eukaryotes, this pathway involves cAMP binding to specialized CRP-like binding domains on protein kinases, calcium channels, and nucleotide exchange factors for small GTPases.

Diguanylate cyclases produce another second messenger, 3',5'-cyclic diguanylic acid (c-di-GMP), which regulates a variety of functions related to the cell surface such as motility, secretion of proteins and polysaccharides, biofilm formation, and production of virulence factors. Some of the c-di-GMP functions are mediated by its binding to dedicated receptors, such as PilZ and MshEN domains, while other functions are regulated through other binding proteins, including diguanylate cyclases themselves and their inactivated variants. Two different types of c-di-GMP-specific phosphodiesterases which catalyze c-di-GMP hydrolysis contain either EAL or HD-GYP domains; their inactivated variants may also function as c-di-GMP-binding protein.

Importantly, these signaling pathways are not entirely separate. In many organisms, there exists a cross-talk between components of different signaling pathways. For example, a significant number of response regulators have adenylate or diguanylate cyclases or c-di-GMP-specific phosphodiesterases as their output (effector) domains, which allows histidine kinase-mediated pathways to affect the cAMP or c-di-GMP levels.

Structural Organization of Signal Transduction Proteins

A key aspect of the bacterial signal transduction machinery is its modular structure. Many signal transduction proteins consist of several distinct protein domains that can be shuffled almost like Lego blocks, resulting in an amazing diversity of proteins.

Sensory Domains

Sensory (signal input) domains of bacterial receptors are diverse and reflect the multiplicity of the signals they perceive. Nevertheless, sequence similarities between sensory domains of different receptors from distantly related organisms allows identification of distinct domain families. Members of the same domain family typically recognize the same—or closely related—ligands. Therefore, characterization of a sensory domain in one organism can be used as a basis for functional annotation of all proteins that contain the same domain. Some sensory domains have a rather narrow ligand specificity, for example, the citrate-binding domain found in the citrate-sensing histidine kinase CitA (DpiB) of *E. coli*. Other sensory domains, such as the periplasmic domain of the *E. coli* dicarboxylate sensor DcuS, which is similar to CitA, bind a number of related molecules such as several C4-dicarboxylates and citrate. For many other domains, the potential ligands—and hence the nature of the sensed molecules—remain unknown. Their potential participation in environmental sensing is deduced primarily from their presence at the N-termini of likely transmembrane receptors.

While most characterized sensory domains are extracellular (periplasmic in Gram-negative bacteria), sequence analyses also identified a number of cytoplasmic and membrane-embedded sensors without extracellular sensing domains (Table 3). Many

Table 3 Examples of bacterial sensory domains

Domain name	Length, aa	Pfam entry ^a	Structure ^b	Ligand specificity
<i>Periplasmic (extracellular)</i>				
SBP_bac_3	~220	PF00497	1lag	Amino acids
NIT	~250	PF08376	4akk	Nitrate, nitrite
PASTA	~55	PF03793	1pyy	β-Lactams
PhoQ_sensor	~180	PF08918	1yax	Ca ²⁺
dCache	~240	PF02743, PF08269, PF14827	4jgo	Citrate, C4-dicarboxylates, other small molecules
sCache	~150	PF16736, PF17200, PF17201, PF17202, PF17203	4exo	pH, Small molecules
CHASE	~220	PF03924	3t4l	Unknown
CHASE2	~240	PF05226	n/a	Unknown
CHASE3	~130	PF05227	3va9	Unknown
CHASE4	~250	PF05228	n/a	Unknown
<i>Membrane-embedded</i>				
5TMR-LYT	~90	PF07694	5TM	Murein derivatives (?) ^c
7TMR-DISM	~200	PF07695	7TM	Unknown
MHYT	~200	PF03707	6TM	NO
MASE1	~280	PF05231	11TM	Redox status
MASE2	~170	PF05230	5TM	Unknown
MASE3	~160	n/a	7TM	Unknown
<i>Cytoplasmic</i>				
PAS	~100	PF00989	1wa9	Heme, flavin, others
GAF	~150	PF01590	1f5m	cGMP, other small molecules
BLUF	~90	PF04940	1x0p	FAD
Globin sensor	~150	PF00042	1or4	Heme (O ₂ , CO, NO)
HNOB	~170	PF07700	1xbn	Heme (NO)
Phytochrome	~180	PF00360	1u4h	Tetrapyrrole

^aPfam database (<http://pfam.xfam.org/>) provides short descriptions of these domains and links to the underlying literature. As an example, the entry page for the domain PF00497 can be found at <http://pfam.xfam.org/family/PF00497>.

^bProtein DataBank (PDB, <http://www.rcsb.org/pdb/>) entry, where available, or the number of transmembrane segments; n/a, not available. Additional structure entries may be listed in the respective Pfam entries. References for the structural entries can be found on the PDB web site (e.g., <https://www.rcsb.org/structure/1lag>) on the NCBI web site (e.g., <https://www.ncbi.nlm.nih.gov/Structure/pdb/1lag>).

^cThe question mark signifies unverified prediction.

sensory domains are detected in more than one receptor type (see below), which is how they often have been identified as sensory domains in the first place. Indeed, if the same periplasmic or membrane-embedded domain is found in two or more different classes of receptors, for example, in histidine kinases and diguanylate cyclases, there is little doubt that this domain serves as a sensor involved in recognition of some ligand(s).

Unfortunately, identification of sensory domains through sequence analysis rarely gives insights into the functions of these domains. Even when such insight is possible, the predicted function must be considered tentative until experimentally verified. For example, *Vibrio cholerae* protein VC0303 (GenBank accession number [AAF93477](#)) belongs to a large family of histidine kinases that contain membrane-embedded N-terminal domains, which are followed by PAS, histidine kinase, and REC domains. The N-terminal membrane domain of VC0303 homologs consists of 12 predicted transmembrane α-helices and is similar to Na⁺/proline and Na⁺/pantothenate symporters (PutP and PanF, respectively). This observation has led to the suggestion that these proteins serve as sensors for the Na⁺ gradient. This suggestion has not been experimentally verified, and members of this family are currently annotated in the protein databases either as sensor histidine kinases (which is correct) or as Na⁺/proline symporters (which is most likely incorrect).

Although the majority of signal transduction pathways respond to environmental cues and employ extracellular (periplasmic) sensor domains, a substantial fraction of bacterial receptors are cytoplasmic without detectable membrane segments. The enzymatic activities of such receptors, which include the *E. coli* nitrate sensor NtrB and *B. subtilis* sporulation regulators KinA, KinB, and KinC, are apparently modulated by intracellular, rather than extracellular, cues. Indeed, many of them contain N-terminal cytoplasmic sensor domains, such as PAS, GAF, or globin sensor domain. The first two of these domains, PAS and GAF, have similar structures, characterized by ligand-binding pocket that can accommodate various small molecules as ligands such as heme, flavin (PAS), cAMP, cGMP (GAF), and others. PAS and GAF domains are often found on the cytoplasmically-located fragments of multidomain bacterial receptors that also contain extracellular sensory domains. For the globin sensor domain, heme is the only known ligand. Heme-containing domains can be sensors of oxygen, carbon monoxide, and NO. In each case, binding of oxygen, CO or NO triggers a significant conformational change that affects interaction of the sensor domain with downstream domains. Thus, the signal generated by oxygen, CO or NO binding is transmitted to the C-terminally located effector domains. This allows PAS-containing

receptors to serve as sensors for the cellular energy state (e.g., *B. subtilis* sporulation-regulating histidine kinase KinA), its redox state (*E. coli* aerotaxis receptor Aer) or oxygen level (*E. coli* c-di-GMP phosphodiesterase Dos). Many receptors display multiple sensor domains, for example, *B. subtilis* KinA with three PAS domains, whose combined mode of action and hierarchy, if any, are unknown.

Of note, not every N-terminal periplasmic or integral membrane domain of a bacterial sensor protein is necessarily involved in signaling. For example, the histidine kinase UhpB, which regulates transport and metabolism of glucose-6-phosphate and related sugars, has a membrane-embedded N-terminal domain that does not bind extracellular glucose-6-phosphate. Instead, this domain interacts with UhpC protein, which is closely related to sugar phosphate transport proteins but actually works as the true sensor of glucose-6-phosphate in the UhpB-UhpC complex. In the *E. coli* histidine kinase KdpD, which regulates membrane transport of K⁺ ions, the function of the membrane segment appears to be limited to anchoring the enzyme molecule in the membrane and ensuring proper interaction between its domains in the cytoplasm, the N-terminal turgor-sensing domain and the C-terminal histidine kinase domain. Thus, for many putative sensory domains, the current functional prediction should be considered at best an educated guess. The nature of the signal(s) that they are sensing needs to be explored in the future.

Structural Organization of Two-component Signal Transduction Systems

Histidine kinases

Histidine kinases are the most numerous and most diverse cellular receptors that control the greatest variety of responses. Almost all of the diversity of histidine kinases arises from the sensory (signal input) domains which can be periplasmic, membrane-embedded or cytoplasmic. A single histidine kinase may contain several sensory domains, for example a periplasmic ligand-binding domain and one or more PAS domains in the cytoplasm (Fig. 2). By contrast, cytoplasmic signal transduction modules of histidine kinases are rather uniform. Analysis of sequence similarities between different histidine kinases by Parkinson and Kofoid in 1992 revealed five conserved sequence motifs, referred to as H, N, G1, F, and G2 boxes. The first of them corresponds to the sequence motif around the conserved phosphoryl-accepting histidine residue in the dimerization and histidine phosphotransfer domain (DHp or HisKA domain in Pfam, Table 4), other boxes correspond to the residues in the ATPase domain (HATPase_c domain in Pfam, see Table 4) that are involved in ATP binding. These motifs are widely used in descriptions of histidine kinases. However, the diagnostic value of these motifs is somewhat restricted by discovery of proteins that lack one or more of these boxes but nevertheless function as histidine kinases, such as *P. aeruginosa* AlgZ/FimS, a sensor protein controlling alginate biosynthesis regulator AlgR, or *Clostridium perfringens* VirS, a sensor protein for the virulence regulator VirR. Cytoplasmic modules of histidine kinases are usually homodimers with each monomer containing both HisKA and HATPase domains (sometimes there are one or more additional domains). The HATPase domain binds ATP and transfers its γ -phosphate to a conserved histidine residue in the H-box of the HisKA domain, either on the same or the other protein chain in the homodimer (cis- or trans-phosphorylation, respectively). The catalytic HATPase domain is always located C-terminally of the HisKA domain.

Several variants of HisKA domains exist, which, despite having similar structures, share limited sequence similarity. The Pfam database currently assigns the HisKA domain the status of a domain group, or a clan, and divides it into four separate domain families, HisKA (PF00512), HisKA_2 (PF07568), HisKA_3 (PF07730), and HWE_HK (PF07536).

In addition to the sensor, HisKA, and HATPase domains, certain histidine kinases contain additional distinct domains. In transmembrane receptors, extracellular (or more precisely, extracytoplasmic) sensor domains are connected to the intracellular signal transduction modules by one or more transmembrane segments and, sometimes, the cytoplasmic helical linker (HAMP) module (Table 4). In addition, some histidine kinases, referred to as hybrid histidine kinases, contain an additional C-terminal phosphoacceptor (receiver, REC) domain with a conserved aspartate residue which is also a part of the signal transduction phosphorelay. Another phosphoacceptor protein domain, histidine phosphotransfer (HPt) domain, has a four-helix-bundle structure, similar to that of HisKA, and similarly contains a conserved histidine residue. The HPt domain can be found at the N-terminus of the protein (e.g., in the chemotaxis histidine kinase CheA), in the middle of it, or at its very C-terminus, see Fig. 2 for examples.

Response regulators

Response regulators of the two-component signal transduction systems are diverse proteins that share the common phosphoacceptor REC domain (often referred to as CheY or CheY-like domain, after its best-known representative). This domain is enzymatically active: it catalyzes both the phosphotransfer from the histidine residue of the HisKA domain to its own conserved aspartate residue, and also its own dephosphorylation. The ratio of these activities of the REC domain of each specific response regulator determines the half-life of the phosphorylated form (CheY~P or, more generally, REC~P) and hence, the fraction of the response regulator molecules that are in the active (phosphorylated) conformation at any given time.

While about 85% of response regulators combine the REC domain with some kind of a signal output domain, approximately 15% represent stand-alone REC domains. This group includes two well-studied proteins, the chemotaxis response regulator CheY of *E. coli* and *S. enterica* and the sporulation regulator Spo0F of *B. subtilis*. Despite obvious sequence and structural similarities and participation in similar phosphorylation-dephosphorylation cycles, these two proteins have strikingly different modes of action. Signal transduction through the first of them, CheY, relies exclusively on protein-protein interactions. Phosphorylation shifts the CheY molecule into a conformation with increased affinity to its target molecule FliM in the flagellar basal body. Thus, phosphorylated CheY shifts the equilibrium of the two forms of FliM resulting in a reversal of flagellar rotation, which is reflected in altered motility patterns. In contrast, Spo0F accepts the phosphoryl group from the sporulation histidine kinase KinA and, in turn, serves as

Table 4 Properties of the signal transduction domains

Signaling system, domain name	Length, aa	Pfam entry ^a	Structure ^b	Protein name, function, comments
<i>Two-component signal transduction</i>				
HATPase	~120	PF02518, PF14501	1bxd	Histidine kinase ATPase domain, phosphorylates the HisKA domain.
HisKA	~120	PF00512, PF06580, PF07536, PF07568, PF07730	1joy	Histidine kinase phosphoacceptor domain, may have a phosphatase activity toward P~REC. Upon dimerization, forms a four-helix bundle. In Pfam, divided into several distinct variants: HisKA, HisKA_2, HisKA_3, and HWE_HK
HAMP	~50	PF00672	2asw	Signal transfer domain. Upon dimerization, forms a four-helix bundle
HPt	~100	PF01627	1tqg	Histidine-containing phosphotransfer domain. Upon dimerization, forms a four-helix bundle
REC	~120	PF00072	2che	Phosphoacceptor domain, dephosphorylates HisKA domains and transfers phosphate to its own Asp residue
<i>Chemotaxis</i>				
MCP signal	~350	PF00015	1qu7	Methyl-accepting chemotaxis protein (MCP), dimerization domain. Upon dimerization, forms a four-helix bundle. Can be reversibly methylated on Glu residues
HAMP	~50	PF00672	2asw	Signal transfer domain. Upon dimerization, forms a four-helix bundle
H_kinase_dim	~67	PF02895	1b3q	Helical bundle domain in chemotaxis histidine kinase CheA
CheW	~140	PF01584		MCP-interacting protein or domain in CheA and CheV-type response regulators
CheB_methylest	~180	PF01339	1chd	MCP-glutamate methylesterase, demethylates the MCPs
CheR	~190	PF01739	1af7	SAdoMet:MCP methyltransferase, methylates the MCPs
<i>Sugar:phosphotransferase system (PTS)</i>				
EI	~570	PF05524 + PF00391 + PF02896	2hwg	PTS enzyme I, catalyzes phosphoenolpyruvate-dependent autophosphorylation and phosphoryl transfer to HPr
PTS-HPr	~90	PF00381	1ptf	Phosphocarrier protein domain
PTS_EIIA_1	~170	PF00358	1gld	PTS enzyme II A protein or domain, accepts phosphoryl residue from HPr and transfers it to EIIB
PTS_EIIB	~80	PF00367	1iba	PTS enzyme II B domain, accepts phosphoryl residue from EIIA and serves as a donor for the sugar substrate
PTS_EIIC	~320	PF02378	3qnq	PTS enzyme II C domain, catalyzes phosphoryl transfer from EIIB to the sugar substrate
<i>Ser/Thr/Tyr protein phosphorylation</i>				
Pkinase	~250	PF00069, PF01163, PF03109	1jwh	Ser/Thr/Tyr protein kinase, autophosphorylates at the expense of ATP and phosphorylates Ser, Thr, or Tyr residues in various target proteins
PP2C	~250	PF00481, PF07228, PF13672	1a6q	Ser/Thr/Tyr protein phosphatase, dephosphorylates Ser, Thr, and/or Tyr residues in protein kinases and other target proteins
<i>cAMP-mediated signaling</i>				
Adenylate_cycl	~600	PF01295	N/A	Adenylate cyclase class I, found in gamma- and deltaproteobacteria, produces cAMP from ATP
Guanylate_cyc	~190	PF00211	1y11	Adenylate cyclase class III, produces cAMP from ATP
cNMPbind	~90	PF00027	1hw5	cAMP/cGMP binding domain
CRP_HTH		PF00325	1hw5	Interaction with the target sites on the DNA
<i>c-di-GMP-mediated signaling</i>				
GGDEF	~180	PF01590	1w25	Diguanylate cyclase, catalyzes c-di-GMP synthesis, inactivated domains serve as allosteric regulators
EAL	~250	PF00563	2bas	c-di-GMP-specific phosphodiesterase, hydrolyzes c-di-GMP, inactivated domains serve as allosteric regulators
HD-GYP	~180	PF01966 + PF13487	4r8z	c-di-GMP-specific phosphodiesterase, hydrolyzes c-di-GMP
PilZ	~100	PF07238	1ywu	c-di-GMP receptor domain
MshEN	~60	PF05157	5htl	c-di-GMP receptor domain
<i>c-di-AMP-mediated signaling</i>				
DisA_N	~120	PF02457	3c1y	Diadenylate cyclase, synthesizes c-di-AMP
DHH, DHHA1	~180	PF01368 + PF02272	5xsn	c-di-AMP-specific phosphodiesterase, hydrolyzes c-di-AMP
7TMR-HD	~220	PF07698	4s1b	c-di-AMP-specific phosphodiesterase, hydrolyzes c-di-AMP
CdAMP_rec	~110	PF06153	4rww	c-di-AMP receptor domain
TrkA_C	~70	PF02080	4xtt	c-di-AMP receptor domain

^aPfam database (<http://pfam.xfam.org/>) provides short descriptions of these domains and links to the underlying literature. As an example, the entry page for the domain PF02518 can be found at <http://pfam.xfam.org/family/PF02518>. Alternative Pfam entries for related domains are separated by a comma. The plus sign indicates several Pfam domains that together form a protein entry.

^bProtein DataBank (PDB, <http://www.rcsb.org/pdb/>) entry; N/A, not available. Additional structure entries may be listed in the respective Pfam entries. References for the structural entries can be found on the PDB web site (e.g., <https://www.rcsb.org/structure/1bxd>) on the NCBI web site (e.g., <https://www.ncbi.nlm.nih.gov/Structure/pdb/1bxd>).

a phosphoryl donor for Spo0B, which further transfers the phosphate to the sporulation response regulator Spo0A. Given the existence of phosphatases that specifically dephosphorylate Spo0F~P, Spo0F appears to serve as a sporulation checkpoint. According to the Response Regulator Census (see Table 1), many bacterial genomes encode multiple response regulators, among them many stand-alone REC domains (for example, there are 42 such genes in *M. xanthus* and 38 in *Solibacter usitatus*). In many archaea, stand-alone REC domains comprise the majority of response regulators. It is likely that some of them, like CheY, transmit the signal through protein–protein interactions, whereas others, like Spo0F, participate in phosphorelays.

With the exception of members of the CheY/Spo0F protein family, all other response regulators are two-domain (or even three-domain) proteins that combine the REC domain with a signal output domain, which is usually located at the C-terminus of the polypeptide chain. Most of these proteins are transcriptional regulators that activate or repress transcription of specific target genes. Accordingly, the most common output domains bind DNA or RNA, although some response regulators have enzymatic or ligand-binding output domains.

The most common DNA-binding response regulators belong to the OmpR/PhoB family and have a winged helix-turn-helix (wHTH) DNA-binding domain (Table 5). The second in abundance is the NarL/FixJ family of response regulators, which have a typical helix-turn-helix (HTH) DNA-binding domain. Less common DNA-binding response regulators contain DNA-binding domains of the Fis type (NtrC and ActR/PrrA families), AraC type (YesN family), LytTR type (LytR/AgrA family), or Spo0A_C type (Spo0A family), among others. There are families of response regulators that are found just in one or two instances in the current databases. In each case, phosphorylation of the REC domain causes changes in its conformation that lead to the formation of a interactive surface (the α 4- β 5- α 5 interface) and also favors its dimerization. Specifically, phosphorylation of the Asp residue (Asp57 in CheY of *E. coli*) causes reorientation of a conserved Ser/Thr residue (Thr87 in CheY of *E. coli*) that forms a hydrogen bond with a phosphate oxygen. In addition, reorientation of a Phe/Tyr residue (Tyr106 in CheY of *E. coli*) positions it between the active site and the α 4- β 5- α 5 interface. Dimerization of response regulators is a key mechanism of the transcriptional regulation by two-component systems, as these dimers have a high affinity to the tandem (or palindromic) transcriptional regulator binding sites on the chromosome.

Within each family of response regulators, the signal specificity is determined by the interaction of the REC domains with their cognate histidine kinases and of the HTH domains with recognition sequences on the DNA. As a result, transcriptional regulators with dramatically different biological functions (e.g., OmpR and PhoB) can possess rather similar sequences. Therefore, sequence-based assignments of biological function are often unreliable, despite confident recognition of the DNA-binding output domains in most response regulators.

Table 5 Signal output domains in bacterial response regulators^a

Regulator family	Output domain	Length, aa	Pfam entry ^a	Structure ^b	% Total ^c	Protein function
<i>Stand-alone</i>						
CheY/Spo0F	None	~120	PF00072	2che	16.8%	Protein–protein interaction, phosphorelay
<i>DNA-binding</i>						
OmpR/PhoB	wHTH	~120	PF00486	1bl0	29.6%	Transcriptional regulation
NarL/FixJ	HTH	~120	PF00196	1rnl	16.5%	Transcriptional regulation
LytR/AgrA	LytTR	~110	PF04397	3bs1	2.9%	Transcriptional regulation
ActR/PrrA	Fis (HTH_8)	~50	PF02954	3fis	1.1%	Transcriptional regulation
AraC/YesN	HTH_AraC	~140	PF00165	1bl0	0.7%	Transcriptional regulation
PhyR	RpoE	~140	PB13556 PF08281	1or7	0.4%	Transcriptional regulation
Spo0A	Spo0A_C	~120	PF08769	1fc3	0.2%	Transcriptional regulation
GlnL	YcbB	~140	PF08664	n/a	0.2%	Transcriptional regulation
<i>Three-domain DNA-binding</i>						
NtrC	AAA, Fis (HTH_8)	~230 ~50	PF00158 + PF02954	1ojl, 3fis	9.7%	Transcriptional regulation
SARP	HTH, BTAD	~220	PF00486 + PF03704	2fez	<0.1%	Transcriptional regulation
<i>RNA-binding</i>						
AmiR/NasR	ANTAR	~55	PF03861	1qo0	1.0%	Regulation of transcription (anti)termination
CsrA	CsrA	~60	PF02599	1vpz	<0.1%	Regulation of translation and mRNA decay
<i>Enzymatic</i>						
CheB	CheB	~180	PF01339	1chd	2.6%	Methylesterase
FlhY	CheC	~200	PF04509	1squ	0.2%	Asp~P phosphatase
<i>Protein-binding</i>						
CheV	CheW	~140	PF01584	1k0s	1.4%	Protein–protein interaction
HDOD	HDOD	~190	PF08668	1vqr	0.2%	Inactivated phosphodiesterase, unknown function

^aThis listing does not include GGDEF, EAL, HD-GYP, AC3, or PP2C output domains, listed in Table 4.

^bProtein DataBank entry, if available; n/a, not available.

^cFraction of the response regulators from this family among 27327 response regulators encoded in complete genomes of 896 prokaryotic species, see Response Regulator Census, http://www.ncbi.nlm.nih.gov/Complete_Genomes/RRcensus.html.

In a significant fraction of response regulators, the output domains have an intrinsic enzymatic activity, such as the methyltransferase domain in the chemotaxis response regulators of the CheB family. These output domains are typically the same as in environmental receptors: adenylate and diguanylate cyclases, *c*-di-GMP-specific phosphodiesterases, PPC2-type Ser/Thr protein phosphatases, and even histidine kinases. These are discussed in detail below. It is important to note, however, that such response regulators put other signaling mechanisms under the control of the two-component signal transduction. Indeed, a response regulator with an adenylate cyclase output domain may control cellular cAMP levels irrespective of the status of receptor adenylate cyclases. This could also be the case for control of *c*-di-GMP. The case of Ser/Thr protein phosphorylation is even more illuminating. Response regulators with the PPC2-type protein phosphatase domain far outnumber those with a protein kinase domain. The two-component signaling system apparently controls the level of Ser/Thr/Tyr protein phosphorylation primarily by regulating the rate of their dephosphorylation.

Certain response regulators consist of more than two domains. In transcriptional regulators of the NtrC family, the N-terminal REC domain and the C-terminal DNA-binding, Fis-like domain are separated by a central AAA-type ATP-binding domain, whose ATPase activity is required for precise DNA-binding. The response regulator VieA from *Vibrio cholerae* contains two output domains, a *c*-di-GMP-specific phosphodiesterase (EAL) and a DNA-binding HTH domain. In that case, the role of the HTH domain remains to be established.

In summary, bacterial response regulators contain a variety of output domains that put the histidine kinases at the top of signaling hierarchy, allowing the cell to control its metabolism and behavior in response to a wide array of conditions.

Alternative Signal Transduction Systems

Methyl-accepting chemotaxis proteins

Methyl-accepting chemotaxis proteins (MCPs) contain a characteristic signal transduction domain (Pfam domain PF00015) that consists of two long antiparallel α -helices, connected via a hairpin at their base. This hairpin serves as a distinct signaling module and contains a characteristic, highly conserved sequence motif, which directly interacts with the chemotaxis histidine kinase CheA, modulating its activity. Thus, in the MCP-CheA assembly, the whole MCP can be considered a sensor domain of CheA. Despite giving the MCP its name, methylation itself does not seem to be a necessary part of the signal transduction mechanism. Rather, methylation (by CheR) and demethylation (by CheB) change the charge distribution along the α -helices and affect the packing of these α -helices against each other, which, in turn, is reflected in the interaction between MCP and CheA. This adds yet another regulatory circuit to the chemotaxis signaling machinery which allows the cells to carry out sensory adaptation after a chemotactic response.

Phosphotransferase system

The phosphoenolpyruvate-dependent sugar:phosphotransferase system (PTS) catalyzes uptake of certain sugars, coupling substrate transport with phosphorylation. In addition to its transport function, the PTS is an important component of the signaling machinery that controls chemotaxis to its sugar substrates. Like histidine kinases, PTS proteins are phosphorylated on histidine residues. However, in contrast to the ATP-His-Asp or ATP-His-Asp-His-Asp phosphorelay, typical for the two-component signaling, the PTS phosphorelay starts from phosphoenolpyruvate (PEP) and only proceeds via His residues, at least until the final step. The high free energy of PEP hydrolysis ensures that in the absence of their carbohydrate substrates all PTS components are phosphorylated. The limiting step in the phosphorelay appears to be PEP-dependent autophosphorylation of the first component, EI. Therefore, in the presence of carbohydrates, phosphoryl flow through the PTS components occurs at a higher rate than rephosphorylation of EI by PEP. As a result, EI, HPr and EIIA components become partly dephosphorylated. This serves as a signal both for the chemotaxis machinery and for the *E. coli* adenylate cyclase. Although any direct interaction between PTS components and MCP or CheA remains to be demonstrated, the data suggest that unphosphorylated EI might interact with one or more MCPs (in *B. subtilis*) or with CheA (in *E. coli*), modulating the CheA activity and, hence, the cellular level of CheY~P. The second mechanism of signal transduction from the PTS involves EIIA^{Glc}. This protein has been shown to interact with the adenylate cyclase and other targets, including lactose permease, typically inhibiting their activities. Interaction of EIIA^{Glc} with the adenylate cyclase inhibits cAMP production and decreases transcription of cAMP-dependent (so-called catabolite sensitive) operons. This effect is often referred to as catabolite repression (see below). Interaction of EIIA^{Glc} with lactose permease inhibits lactose uptake, diminishing the cellular levels of allolactose, the inducer of the lactose operon. This effect is referred to as inducer exclusion. These two effects of EIIA^{Glc} combine to prevent utilization of certain sugars (such as lactose in *E. coli*) in the presence of a preferred sugar (such as glucose in *E. coli*). Inducer exclusion can be observed in many PTS-encoding organisms that lack the adenylate cyclase, such as *B. subtilis*. In some organisms, PTS-mediated signaling includes additional control mechanisms, such as reversible phosphorylation of the HPr protein on its Ser residue, which affects the ability of this protein to participate in the PTS phosphorelay.

Ser/Thr/Tyr protein kinases and protein phosphatases

Reversible protein phosphorylation on serine, threonine, or tyrosine residues is a key regulatory mechanism in eukaryotic cells. In the past several years, Ser/Thr/Tyr protein kinases have been recognized in a variety of bacterial and archaeal cells as well but nevertheless are often referred to as “eukaryotic-type” protein kinases. Ser/Thr/Tyr protein kinases are encoded in multiple copies in many bacteria, particularly in *Actinobacteria* and *Cyanobacteria*; the genomes of *M. xanthus* and *Sorangium cellulosum* encode more

than 100 of them, almost as many as histidine kinases. In many archaea, Ser/Thr/Tyr protein kinases appear to be the principal type of receptors. Despite their abundance, Ser/Thr/Tyr protein kinases are still poorly studied; only a handful of their targets have been recognized and the importance of this kind of regulation often gets overlooked. A recent survey of phosphorylated proteins in *B. subtilis* suggested that most glycolytic enzymes, as well as several enzymes of the tricarboxylic acid cycle and the pentose phosphate pathway, are subject to phosphorylation on serine or threonine residues and, theoretically, could be subject of regulation by Ser/Thr/Tyr protein kinases. Given that *B. subtilis* genome encodes only four Ser/Thr/Tyr protein kinases, they might have rather wide substrate specificity.

Bacterial Ser/Thr/Tyr protein phosphatases are primarily of the PP2C-type. Cellular targets for most of them remain unknown, although some of them have been shown to reverse the action of their cognate Ser/Thr/Tyr protein kinases, possibly by dephosphorylating the kinases themselves.

Adenylate cyclases

Adenylate (adenylyl) cyclases, the enzymes that produce cAMP from ATP, exist in several unrelated variants, referred to as classes. Traditionally, the enzyme from *E. coli* is considered class I adenylate cyclase. This protein appears to be associated with the cell membrane but does not seem to directly sense any environmental signals. However, its activity is modulated by the EIIA^{Glc} component of the glucose-specific phosphotransferase system (PTS). The phosphorylated form of EIIA^{Glc} appears to activate adenylate cyclase, whereas the dephosphorylated form, which accumulates in the presence of extracellular glucose, does not activate adenylate cyclase and might even inhibit it. Thus, in the presence of glucose or other PTS sugars, adenylate cyclase activity decreases, leading to a drop in cAMP level. This is one of the mechanisms contributing to the phenomenon of catabolite repression.

Bacterial receptor-type adenylate cyclases belong to the so-called class III and were first described in 1996 in the cyanobacterium *Spirulina* (current name *Arthrospira*) *platensis*. Analysis of the gene sequence predicted that its product contains a signal peptide, a periplasmic sensor domain, a membrane-spanning domain and an adenylate cyclase-like catalytic domain. A similar gene from another cyanobacterium, *Anabaena* sp. PCC7120, was shown to complement a *cya*[−] mutant of *E. coli*, indicating that it encoded an active adenylate cyclase domain. Receptor-type adenylate cyclases were later found to play regulatory roles in a variety of bacteria, including *Mycobacterium tuberculosis*. Some of them are located in the cytoplasm, while others have extracytoplasmic or membrane-embedded sensor domains. One of them, the *P. aeruginosa* protein CyaB (PA3217), proved to be a key regulator of the expression of virulence factors, contributing to mouse infection by this bacterium. Ligands for these receptor adenylate cyclases have not yet been identified.

In eukaryotes, many class III adenylate cyclases possess limited substrate specificity and partially accept GTP as a substrate producing cGMP, a second messenger on its own that controls the activities of protein kinases, calcium channels, and other proteins. Similar enzymes, predominantly producing cGMP, have been reported in several bacteria, with cGMP apparently used as a second messenger for such developmental processes as cyst formation in *Rhodospirillum centenum* and biofilm formation in *Xanthomonas campestris*. The issue of bacterial cGMP signaling remains highly controversial, in particular because the intracellular concentration of ATP far exceeds that of GTP.

Diguanylate cyclases and c-di-GMP phosphodiesterases

A widespread group of bacterial membrane receptors includes proteins with GGDEF, EAL, and HD-GYP signal transduction domains that synthesize and hydrolyze the second messenger c-di-GMP. These proteins have been initially recognized as sensor proteins through computational analysis of bacterial genomes. Subsequent experimental studies revealed their role in regulating biofilm formation, development of flagellar apparatus, and a variety of other processes.

The GGDEF domain, so named after a conserved Gly-Gly-Asp/Glu-Glu-Phe sequence motif, is a diguanylate cyclase that synthesizes c-di-GMP from two molecules of GTP. This enzyme only works as a dimer with each monomer binding a GTP molecule (see Table 4). Hydrolysis of c-di-GMP is carried out by two different classes of c-di-GMP-specific phosphodiesterases, referred to as the EAL and HD-GYP domains, also named after their conserved sequence motifs. The HD-GYP domain (HD_5 in Pfam) is a member of the widespread HD phosphohydrolase domain family that contains an additional C-terminal subdomain.

Almost a half of GGDEF domains and two-thirds of all EAL domains are found in fused proteins that contain both GGDEF and EAL domains. The overall activity of these fusion proteins can be either synthesis or hydrolysis of c-di-GMP, as has been observed when these proteins were first characterized in 1998 by M. Benziman and colleagues. It appears that in many such fusion proteins, at least one of the domains is enzymatically inactive and serves as an allosteric regulator of the other one. In some cases, however, both domains appear to be active. While many GGDEF, EAL, and HD-GYP domains comprise the signal transduction modules of membrane-anchored environmental sensors, others are found in cytoplasmic proteins, including many response regulators.

Diadenylate cyclases

Cyclic diadenosine 3′-5′ monophosphate (c-di-GMP) is a recent addition to the list of bacterial second messengers. It was originally discovered as a molecule that signals the DNA integrity in *B. subtilis*, an important checkpoint before the cell enters the sporulation process. In non-spore-forming *Listeria* spp. and *Staphylococcus* spp., synthesis of c-di-GMP served as a signal of the cell wall stress and was essential for cell viability. Cyclic di-AMP appears to regulate the osmotic pressure inside the bacterial cell through its control of potassium ion transport. The c-di-GMP-producing diadenylate cyclase DisA_N domain is encoded in a variety of bacteria and archaea, suggesting that c-di-GMP might be the most widespread second messenger in the prokaryotic world.

Interaction of Signal Transduction Pathways

As mentioned above, different classes of bacterial receptors often contain similar sensory domains. This phenomenon is often observed between different groups of organisms. Thus, histidine kinases with CHASE4 sensor domain are found mostly in archaea, whereas diguanylate cyclases with CHASE4 domains are found exclusively in bacteria (see Table 6). This suggests that different organisms employ different signaling pathways and, ultimately, different mechanisms to respond to similar environmental cues. For example, *Thiomicrospira denitrificans* sensing extracellular nitrate by a NIT sensor histidine kinase (Table 6) would generate an intracellular response, transcriptional or otherwise, modulated by its cognate response regulator. *Shewanella amazonensis*, which encodes a NIT-coupled MCP, would respond to nitrate by chemotaxis, whereas *Chromobacterium violaceum*, encoding a NIT-coupled diguanylate cyclase, most likely reacts to nitrate by adjusting its motility speed and/or polysaccharide secretion. Thus, the diversity of signal transduction pathways ensures that different organisms respond to similar—or even identical—environmental signals with differentiated cellular responses. These responses may be particularly complex in free-living organisms with large genomes, which encode a large number of signal transduction proteins. In such organisms, diverse receptors with common sensory domains often coexist, allowing a sophisticated multilevel response to environmental cues. For example, the genome of *Anabaena* sp. PCC 7120 encodes 13 proteins with the periplasmic CHASE2 domain, including four histidine kinases (All1178, All3347, All5309, and Alr5151), two Ser/Thr/Tyr protein kinases (All4838 and Alr1869), an adenylate cyclase (All1118), and a diguanylate cyclase (All1219). Although the environmental signal sensed by the CHASE2 domain has not been identified, there are certain indications that it might be osmolarity or a related parameter.

Another mechanism of cross-talk between signaling pathways involves response regulators with enzymatic output domains. For example, signals sensed by the *P. aeruginosa* methyl-accepting protein WspA are transmitted through the hybrid histidine kinase WspE to the response regulator WspR that has a diguanylate cyclase (GGDEF) output domain and regulates biofilm formation. This way, signals from receptors such as MCPs or histidine kinases may end regulating a variety of diverse processes.

In addition, genome analysis reveals numerous cases of signaling proteins that combine different kinds of signal transduction domains, for example, an adenylate cyclase with a Ser/Thr/Tyr protein kinase. Such proteins are difficult to annotate, let alone figure out their cellular functions. Nevertheless, preservation of such multidomain proteins through millions of years of evolution indicates that they do have a function, at least in some environmental conditions. It is reasonable to suggest that the extreme diversity of signal transduction proteins, generated through numerous combinations of core protein domains, reflects different paths of adaptation to their environment.

How Bacteria See the World

Despite many years of studies, our understanding of signal transduction pathways is still limited, even in the best-studied model organisms such as *E. coli* and *B. subtilis*. We still lack the complete understanding which environmental parameters these organisms sense, let alone why they choose these parameters and not others. However, the availability of complete genomes provides us with an opportunity to list the components of the signaling network and start analyzing and modeling their respective contribution to the regulation of gene expression and cellular behavior. Back in 1999, James Hoch and colleagues published a review on two-component signal transduction in *B. subtilis* (see Further Reading) entitled “How one organism sees its world.” In the same fashion, it could be instructive to look at the genome of *E. coli* and see what receptors it uses to monitor the environment and the intracellular milieu. To the best of our knowledge, the signal transduction machinery of *E. coli* includes the following components:

- 30 histidine kinases with 34 response regulators
- 23 membrane components of the sugar PTS
- 12 diguanylate cyclases
- 10 c-di-GMP phosphodiesterases
- 7 proteins with both GGDEF and EAL domains
- 5 methyl-accepting chemotaxis proteins
- 2 predicted Ser/Thr protein kinases
- 1 class I adenylate cyclase

How much do we know about their functions? The signals sensed by each of the five MCPs have been experimentally determined:

- Tsr—serine
- Tar—aspartate, maltose
- Trg—ribose, galactose
- Tap—dipeptides, pyrimidine
- Aer—redox state of the respiratory chain

The last of these MCPs, Aer, is obviously important for sensing the presence of usable terminal electron acceptors, reflecting the choice between a respiratory and fermentative metabolism. The ligands sensed by the other four MCPs include amino acids, peptides, and sugars. However, it is hard to say why evolution has chosen these particular ligands over other amino acids and sugars.

^aThe domain names are as in Tables 3 and 4. Each cell contains an example of a protein with the specified domain combination, listed by its gene name (locus tag) or accession number in the NCBI protein database. The names in italics indicate domain combinations found so far only in eukaryotes. Dashes indicate domain combinations not found in the NCBI protein database as of 31 December 2017.

For example, why serine and aspartate are more important for chemotaxis than glutamine and asparagine, which link carbon and nitrogen metabolism? Likewise, why maltose and galactose and not glucose or fructose? A partial answer to the second question is given by the listing of substrates of the sugar PTS, which serves as an MCP-independent mechanism of regulating chemotaxis towards sugars:

- FruA, FrvB, FrwC, HrsA, YpdG—fructose
- AscF, CelB—cellobiose (β -D-Glu-D-Glu)
- MtlA, CmtA—mannitol
- GatC, SgcC—galactitol
- AgaC/D, AgaW—*N*-acetylgalactosamine
- NagE—*N*-acetylglucosamine
- ManX/Y—mannose
- SrlA—sorbitol
- PtsG—glucose
- MalX—maltose (α -D-Glu-D-Glu)
- TreB—trehalose (α -D-Glu-D-Glu)
- GlvC— α -glucosides
- BglF— β -glucosides
- SgaB—ascorbate
- YfeV—*N*-acetylmuramic acid

Thus, *E. coli* carries in its genome genes encoding chemotaxis receptors for almost any commonly found monosaccharide and several disaccharides. Whether these genes are constitutively expressed at sufficient levels to contribute to the cell behavior remains an open question. It appears that at least for some of the PTS receptor genes need to be induced by the corresponding sugar.

Regarding transcriptional regulation, signals for 28 out of 30 histidine kinases have been characterized. These signals (ligands) are as follows:

- CheA—chemotaxis, perceives signals from MCPs
- AtoS—acetoacetate, histamine, spermidine
- BaeS, BasS, CpxA, EvgS, RcsC, RscD—envelope stress
- EnvZ, KdpD—osmotic stress, K^+ gradient
- PhoM, PhoQ, PhoR—phosphate (and/or Ca^{2+} , Mg^{2+})
- NarQ, NarX—nitrite/nitrate
- CusS, ZraS—heavy metals (Cu^+ / Ag^+ , Zn^{2+} / Pb^{2+})
- ArcB, BarA—redox stress, O_2 , H_2O_2
- CitA—citrate
- DcuS—fumarate, C4-dicarboxylates
- UhpB—glucose-6-phosphate
- GlnL—glutamine
- TorS—trimethylamine oxide
- QseC—quorum sensing
- BtsS (formerly YehU)—amino acids, peptides
- GlrK (formerly YfhK)—epinephrine, sulfate
- YpdA—pyruvate

The signals for the remaining two histidine kinases, RstB and YedV, remain unknown. RstB is apparently activated by stress but the exact effector has not been identified. YedV, along with CusS, participates in copper homeostasis but binding of Cu^+ ions to the protein remains to be demonstrated. It is remarkable how many histidine kinases are sensing either envelope and osmotic stress or redox state of the cell and the availability of terminal electron acceptors. The fact that these histidine kinases coexist in the same cell suggests a certain degree of sophistication in their interactions, seen, for example, in the complex division of functions between NarQ and NarX. In most cases, however, the hierarchy between different sensors, if any, remains unknown.

Our current knowledge of the functions of 29 *E. coli* proteins with GGDEF and/or EAL domains that function as diguanylate cyclases and/or c-di-GMP-specific phosphodiesterases is more limited. The sensed ligand, oxygen (and potentially CO and NO), has been established for two of them, “direct oxygen sensors” DosP (formerly YddU) and DosC (formerly YddV). The diguanylate cyclase DgcZ (YdeH) senses zinc ions and BluF (YcgF) senses blue light. Five c-di-GMP phosphodiesterases, PdeB, PdeC, PdeG, PdeN, and PdeT, contain the CSS-motif sensor domain that can exist in dithiol and disulfide forms and appears to sense the redox status of the periplasm. The phosphodiesterase PdeF (YfgF), which has the MASE1 periplasmic sensor domain, senses aspartate, and three other *E. coli* enzymes, diguanylate cyclases DgcE and DgcF and the phosphodiesterase PdeA, which all contain the same MASE1 sensor domain, could be predicted to sense aspartate as well (and/or a closely related molecule). The N-terminal GAF domain of the DgcP likely regulates the c-di-GMP synthase activity of its downstream GGDEF domain by binding cAMP or a similar ligand. Several other GGDEF and/or EAL domain proteins, such as DgcC (AdrA), DgcM, PdeR, and CsrD, have been shown to regulate, respectively,

cellulose biosynthesis, production of curli fimbriae, and carbon storage. RflP (YdiV) and PdeH (YhjH) regulate flagellar motility. For other GGDEF and/or EAL domain proteins (YcdT, YeaI, YeaJ, YedQ, YfiN, YhjK, YliF, YahA, and YliE), neither the sensed signal nor the regulated process are known at this time, although their overexpression leads to the expected changes in c-di-GMP levels, which affect motility and biofilm formation.

The situation with the two predicted Ser/Thr/Tyr protein kinases of *E. coli* is not much better. Although these proteins have been identified as members of the Ser/Thr protein kinase superfamily and have all the key active site residues intact, neither of them has been actually shown to function as a Ser/Thr protein kinase. One of them, UbiB, is required for a hydroxylation step in ubiquinone biosynthesis and was initially thought to function as 2-octaprenylphenol hydroxylase. However, this enzymatic activity has not been experimentally demonstrated. Instead, this activity has been demonstrated in a different protein, VisC, renamed UbiI. Thus, UbiB is probably not an enzyme of ubiquinone biosynthesis but a Ser/Thr protein kinase that regulates this process. The functions of the second predicted Ser/Thr protein kinase, YegI, remain unknown.

Summing up, there remain major puzzles even in signal transduction pathways of *E. coli*. For most other free-living bacteria, as well as for most archaea, understanding the signal transduction mechanisms and pathways will remain a challenge for years to come.

Glossary

Adnexa In this context, usually refers to the fallopian tubes and ovaries.

Ectopic pregnancy A pregnancy that occurs outside of the uterus, such as in a fallopian tube or ovary, often resulting in extensive damage to the affected organ.

Endometritis Inflammation of the inner lining of the uterus.

Epidemiology The study of the factors determining the frequency and distribution of disease in a community, and the relationships among those factors.

Epididymitis Sometimes painful inflammation of the epididymis, often resulting from infection.

Incidence The rate at which new cases of a disease occur in a community over a given time period.

Lymphangitis Inflammation of the lymph nodes and associated lymphatic ducts that occurs as a result of infection at a distal site.

Orchitis Testicular inflammation.

PID Pelvic inflammatory disease (PID) is a term referring to endometritis, an infection with inflammation in the fallopian tubes, tubo-ovarian abscess, peritonitis, or any combination of these findings.

Prevalence The total number of cases of a given disease in a community at a given time.

[☆]*Change History:* August 2014. KG Ghanem and TC Quinn have updated all epidemiology sections; gonorrhea diagnosis; gonorrhea treatment; chlamydia diagnosis; chlamydia treatment.

This article is an update of J.A. Cecil, T.C. Quinn, Sexually Transmitted Diseases, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 717–733.

Defining Statement

The term ‘Sexually transmitted diseases (STDs)’ refers to a large number of distinct infections, which are typically transmitted through sexual contact and result in a wide variety of illnesses. This article summarizes some important epidemiological trends among the more common STDs, and reviews the clinical syndromes, diagnosis, treatment, and pathogenesis of some select STDs.

Introduction

Over the past three decades, there have been tremendous advances in our understanding of sexually transmitted diseases (STDs). There has been recognition of new pathogens, new clinical syndromes, emerging antimicrobial resistance, the increasing importance of viral pathogens, and a better understanding of the epidemiology of many STDs, and progress has been made in the field of prevention including vaccine development. There are approximately 50 distinct clinical syndromes associated with more than 30 different sexually transmissible organisms. [Table 1](#) summarizes some of the most important pathogens, the associated clinical syndromes, and potential complications.

Even apart from the HIV epidemic, STDs constitute a significant public health problem worldwide, despite improvements in diagnosis, treatment, and prevention strategies. STDs are seen in virtually every society, though developing nations and underserved populations experience the greatest burden of disease. According to 2008 World Health Organization (WHO) estimates, there were nearly 500 million new cases worldwide of curable STDs in adults aged 15–49 years. The global prevalence of infection with the agents of common viral STDs, such as genital herpes simplex virus, genital human papillomavirus, hepatitis B, and HIV, is estimated to be in the billions, as many individuals are infected with more than one of these pathogens. According to the WHO, in developing countries STDs and their complications comprise the top five disease categories for adults seeking medical care. In the United States, the Centers For Disease Control And Prevention (CDC) estimates that there are approximately 20 million new cases of STDs annually, nearly half of them occurring among young people aged 15–24 years. Of reportable infectious diseases in the United States, chlamydia and gonorrhea remain the top two most common diseases reported to the CDC. According to CDC surveillance data, there were 107.5 cases of gonorrhea per 100 000 people and 456.7 cases of chlamydia per 100 000 people in 2012. Both of these rates represented an increase from the previous year.

STDs are recognized as a source of tremendous social, health, and economic costs worldwide. There are many factors contributing to the disease costs exacted by STDs. Challenges to the control of STDs include limitations on the availability and quality of medical care, public education regarding safer sexual practices, access to condoms and other methods of prevention, convenient and affordable methods of diagnosis and treatment, the emergence of antibiotic resistance, and the social stigma associated with STDs. Furthermore, STDs are commonly asymptomatic in both women and men. All of these factors can result in a delay or complete lack of appropriate treatment, with implications for ongoing transmission of infection to sexual partners.

The largest share of the disease burden from STDs is a result of the complications and sequelae that may follow initial infection. When left untreated, infections can migrate upward from the lower reproductive tract and result in pelvic inflammatory disease (PID), chronic pelvic pain, infertility, ectopic pregnancy and tubo-ovarian abscess in women, and prostatitis, epididymitis, or orchitis in men. It has been estimated that the economic cost of PID alone exceeds \$2 billion per year in the United States. In 2010, direct medical costs associated with STDs in the United States were estimated at up to \$16 billion annually. Untreated infections in pregnant women may lead to fetal loss, stillbirths, low birth weight, and eye, lung, or neurologic damage in a newborn. The viral STDs are typically incurable and result in chronic disease, often associated with significant morbidity and mortality. The most obvious example of this is HIV infection and AIDS. Another example is human papilloma virus (HPV), some types of which are known to cause cervical cancer in women. Cervical cancer is the second leading cause of female cancer mortality worldwide.

In general, the major STDs pose a greater threat to women’s health than to men’s, for a number of reasons. Women are more likely to get an STD from a man than the other way round because STDs are generally more efficiently transmitted from men to women. Women are more likely to be asymptomatic than men, and thus women may be less likely to seek timely medical attention. STDs are often more difficult to accurately diagnose in women than in men because symptoms are less specific and diagnostic tests are less sensitive. Finally, the potential complications of STDs are more common and more serious in women.

Studies of the epidemiology of STDs have revealed several risk factors consistently associated with the acquisition of STDs. These risk factors appear to apply to most, if not all, populations. Risk factors include multiple sexual partners, urban residence, single marital status, and young age. The risk of STDs for young adults and adolescents has not been fully appreciated by the public and by policy makers. STD prevention efforts in young people have remained controversial in the United States despite the fact that approximately 3 million teenagers acquire an STD each year. The CDC estimates that one in four young women in the United States between the ages of 14 and 19 is infected with at least one of the most common STDs, namely HPV, chlamydia, or trichomoniasis. Young adults and adolescents are at greatest risk for acquiring an STD for a number of reasons, related to patterns of sexual behavior and other behaviors associated with STDs, such as substance abuse. There is some evidence that biological factors may also play a role in young women. Thus, any successful STD prevention program needs to specifically include this population, and multiple groups including the CDC recommend annual screening for chlamydia and gonorrhea at a minimum in all sexually active women under 26 years of age, whether or not they report symptoms. With the development of an effective

Table 1 Major sexually transmitted organisms and associated diseases

Agent	Disease or syndrome
<i>Bacteria</i>	
<i>Neisseria gonorrhoeae</i>	Urethritis, epididymitis, prostatitis, proctitis, Bartholinitis, cervicitis, conjunctivitis, pharyngitis, PID and related sequelae (infertility and ectopic pregnancy), perihepatitis, complications of pregnancy (e.g., chorioamnionitis, premature rupture of membranes, premature delivery, and postpartum endometritis), DGI associated with bacteremia, endocarditis, arthritis
<i>Chlamydia trachomatis</i>	Urethritis, epididymitis, prostatitis, proctitis, Bartholinitis, cervicitis, conjunctivitis, pharyngitis, PID and related sequelae (infertility, ectopic pregnancy), perihepatitis, complications of pregnancy (e.g., chorioamnionitis, premature rupture of membranes, premature delivery, and postpartum endometritis), LGV, proctocolitis (serovars L1, L2, or L3) ^a ; Reiter's syndrome, infant pneumonia
<i>Treponema pallidum</i>	Syphilis ^a (see text for further discussion)
<i>Haemophilus ducreyi</i>	Chancroid ^a
<i>Klebsiella granulomatis</i>	Granuloma inguinale/donovanosis ^a
<i>Mycoplasma hominis</i>	Postpartum endometritis
<i>Mycoplasma genitalium</i>	Urethritis, cervicitis, endometritis, PID
<i>Ureaplasma urealyticum</i>	Urethritis and postpartum endometritis
<i>Gardnerella vaginalis</i> , <i>Mycoplasma hominis</i> , and anaerobic bacteria (<i>Mobiluncus</i> sp. and <i>Prevotella</i> sp.)	Bacterial vaginosis and intraamniotic infection syndrome in pregnancy
Group B β -hemolytic streptococci ^b	Neonatal sepsis and neonatal meningitis
<i>Viruses</i>	
HSV-1 and HSV-2	Primary and recurrent genital herpes, urethritis ^a , proctitis, and meningitis and encephalitis in infants
HBV and HCV	Acute, chronic, or fulminant hepatitis, with associated immune complex phenomena and long-term sequelae, including cirrhosis and hepatocellular carcinoma in chronic active infection
CMV	Congenital infection: gross birth defects and infant mortality, cognitive impairment (e.g., mental retardation and 8th nerve deafness), heterophile-negative infectious mononucleosis, potential multiorgan disease in the immunosuppressed host
HPV	Condyloma acuminata/genital warts and respiratory tract warts in infants (recurrent respiratory tract papillomatosis), HPV types 6 and 11 most commonly; cervical cancer and other anogenital cancers, most commonly associated with HPV types 16 and 18
MCV	Genital molluscum contagiosum
Human immunodeficiency virus (HIV-1 and HIV-2)	AIDS and related complications
Human T-lymphotropic virus type 1	T-cell leukemia/lymphoma and tropical spastic paraparesis
<i>Protozoa</i>	
<i>Trichomonas vaginalis</i>	Vaginitis and urethritis
<i>Fungi</i>	
<i>Candida albicans</i>	Vulvovaginitis and balanitis
<i>Ectoparasites</i>	
<i>Phthirus pubis</i>	Pubic lice infestation
<i>Sarcoptes scabiei</i>	Scabies

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; DGI, disseminated gonococcal infection; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papilloma virus; HSV, herpes simplex virus; LGV, lymphogranuloma venereum; MCV, molluscum contagiosum virus.

^aThese infections are responsible for the syndrome known as genital ulcer disease.

^bGroup B β -hemolytic streptococcus is not believed to be sexually transmitted *per se*, but vaginal colonization is associated with recent sexual activity, more frequent sexual activity, and with multiple partners.

vaccine against clinically important types of human papillomavirus, the CDC now recommends that all individuals between the ages of 11 and 26 years be vaccinated.

Another factor associated with the acquisition of an STD is a history of prior STD infection. It is estimated that 40% of the annual incidence of chlamydial and gonococcal infections in the United States occur in adolescents who have had these infections previously, and thus repeated screening is important in this population. Similarly, simultaneous infection with more than one STD is not uncommon. In fact, several studies have found that up to 25% of individuals with gonorrhea are also infected with *Chlamydia trachomatis*. On the basis of these data, treatment recommendations include antibiotics that are effective against both organisms.

The control of STDs has become an even higher public health priority in the setting of the HIV epidemic. STDs and HIV share many behavioral risk factors, and thus efforts at educating individuals to eliminate high-risk behaviors and adopt safer sexual practices may help reduce the incidence of both STDs and HIV. In addition, many studies have clearly documented that both ulcerative and nonulcerative STDs increase the risk of HIV transmission. Thus, an individual with both HIV and another STD is more likely to transmit HIV to a sexual partner, as compared with an HIV-infected individual without another STD. Similarly, an HIV-

uninfected individual with another STD is more likely to get HIV from an HIV-infected sexual partner than if he or she did not have an STD at the time of sexual exposure. In a study from Malawi by Cohen and colleagues, urethritis, particularly that due to gonorrhea, was associated with eightfold higher concentrations of HIV-1 RNA in semen than in HIV-infected men without urethritis. The association between STDs and HIV is further strengthened by the findings of an STD treatment study in Tanzania by Grosskurth and colleagues, where communities provided with improved STD diagnosis and treatment experienced a substantial reduction in the incidence of HIV, as a result of a decrease in sexual transmission.

Fortunately, many recent advances have been made in the field of STDs. Intensive research efforts have yielded improvements in the clinical recognition, microbiologic diagnosis, treatment, and prevention of STDs. Epidemiologic data have helped to identify high-risk populations, and thus prevention programs and resources can be appropriately targeted. New clinical algorithms have aided in the early recognition of PID, urethritis, cervicitis, and vaginal infections. Newer diagnostic assays are more rapid, sensitive, and specific for diagnosis of diseases caused by specific pathogens. The development of nucleic acid amplification tests (NAATs) for some STDs has enabled health care providers to quickly, easily, and accurately screen large numbers of individuals for certain STDs, even in the absence of symptoms, with little discomfort or inconvenience to the individual. This has made it possible to identify and treat those individuals who may be more likely to transmit infection or to develop complications, because they would not be prompted to seek health care in the absence of symptoms. Finally, newer antibiotics ensure the possibility of effective treatment of many STDs, including those that have become resistant to older therapeutic agents.

There have been several important developments in the area of STD prevention. The Food and Drug Administration (FDA) has licensed two vaccines effective against clinically important types of HPV. HPV infection is the most common STD in the United States, with an estimated 79 million people currently infected and approximately 14 million new infections each year. As many as half of these infections occur in individuals aged 15–24 years. The development of a vaccine has been an especially important advance, because although many of these infections are asymptomatic and transient, about 10% of women develop persistent infection. Chronic infection with certain types of HPV can lead to cervical cancer, which is one of the most common cancers in women worldwide. Cervical cancer disproportionately affects women of lower socioeconomic status, who are often without medical insurance or regular access to health care; hence, the development of an effective vaccine has great implications for cancer prevention in women in underserved populations. Vaccination is also effective at preventing hepatitis A and B infections, both of which can be transmitted sexually. Hepatitis B is frequently transmitted sexually, and hepatitis B vaccination is recommended for all individuals not previously infected or vaccinated who are being evaluated for an STD. The hepatitis B vaccine is also now routinely recommended as part of childhood vaccinations. Hepatitis A vaccine is recommended for men who have sex with men (MSM) and illicit drug users. Efforts to develop effective vaccines against herpes simplex virus 2 and HIV have thus far been unsuccessful, but are ongoing. An emphasis on consistent condom use remains a mainstay in efforts to prevent most STDs; however, data suggest that concomitant use of the spermicide nonoxonyl-9 might be associated with increased HIV transmission.

Unfortunately, there have been several troubling trends in the field of STDs as well, particularly with regard to emerging drug resistance among several STDs. In recent years the prevalence of antibiotic resistance among isolates of *Neisseria gonorrhoeae* has been increasing and becoming more widespread in the United States. As of April 2007, fluoroquinolones, once a mainstay of treatment for gonorrhea, are no longer recommended by the CDC for the treatment of gonococcal infections and associated complications including PID. In 2004, several cases of treatment failure among individuals with syphilis who were treated with azithromycin were reported and resistance to azithromycin was identified in the United States. Currently, the CDC recommends that gonorrhea be treated with two drugs: an injectable cephalosporin and either oral azithromycin or oral doxycycline.

The STDs discussed in this article have been selected because they are among the more common STDs. In addition, they are illustrative of important variations in epidemiology, diagnosis, treatment, prevention, and pathogenesis, concepts that are central to our understanding of STDs. Additional information regarding '*Chlamydia*', 'Polymaviruses and Papillomaviruses', 'herpesviruses', and 'Syphilis, historical' can be found in related articles.

Gonorrhea

Epidemiology

Despite previous declines in new cases of gonorrhea, it remains the second most commonly reported infectious disease in the United States. The greatest number of cases reported to the CDC was 1 013 436 in 1978. Over the following years, there was an approximately 74% decline in reported cases, reaching an all-time low in 2009. More recently the number of cases has increased slightly in the United States. A 9.6% increase was observed from 2011–2012 according to the CDC, with 334 826 reported cases of gonococcal infections. These numbers most likely underestimate the true prevalence of gonorrhea in the United States, given that many health care workers do not comply with reporting guidelines and many patients are treated empirically without confirmatory diagnostic testing because of highly suggestive symptoms or known exposure. It is believed that approximately twice as many new infections occur each year as are reported. Estimates of disease burden attributable to gonorrhea are even less reliable in many developing countries. Available data suggest, however, that gonorrhea remains relatively common in the developing world as it does in the United States. According to the WHO, the global estimated incidence of gonorrhea is 106 million infected people annually.

The overall decline in cases since 1976 has been suggested to be due, in part, to a national control program and to the HIV epidemic and the subsequent decrease in high-risk behaviors seen in many segments of the population. An increase in condom use, screening of asymptomatic individuals at risk for gonorrhea, and contact tracing used to identify individuals who are at risk for

gonorrhea given a known exposure to an infected individual are also factors believed to have contributed to the decline in gonorrhea cases. In the United States, however, the decline in gonorrhea cases has not been observed consistently throughout the population. The most striking decline in gonorrhea had been among MSM and white men and women. In contrast, smaller declines have been observed among urban, minority segments of the population, primarily African American and Hispanic. Greater declines have been observed among older age groups as compared with the young. High rates still persist, however, particularly among adolescents and young adults and among racial minorities. In 2012, the rate among African Americans was 462 cases per 100 000 population—almost 15 times higher than among whites. Between 2008 and 2012, gonorrhea rates decreased 15.5% among African Americans but increased 62% among American Indians/Alaska Natives, 34% among Native Hawaiians/Other Pacific Islanders, 23% among whites, and 19% among Hispanics.

Several factors have been shown to correlate with an increased risk of gonorrhea. Gonorrhea is more common among African Americans. According to the CDC, in 2012 the rate of gonococcal infections was 15 times higher for African Americans than for whites. This may be due in part to relatively limited access to quality health care and poverty, in addition to higher prevalence rates in this population; however, some of this disparity may also be a result of greater attendance of minority individuals at public health clinics, where reporting of cases is much better than in other health care settings. Young age is also a risk factor for gonorrhea, as it is for most STDs, and in fact half of all new sexually transmitted infections occur in young people 15–24 years of age. According to 2012 CDC surveillance data, the overall highest rate of gonococcal infections occurred among individuals 20–24 years of age. Young women seem to be at particularly high risk for gonorrhea. In 2012, women aged 15–19 and 20–24 years had the highest rates of gonococcal infection, that is, 521.2 and 578.5 cases per 100 000 people, respectively. This may be due in part to patterns of sexual behavior, but there may also be a biologic basis to this observation in that young women have larger areas of cervical ectropion (columnar epithelial cells on the ectocervix) that provide a greater surface area susceptible to infection than in older women. Low socioeconomic status, early onset of sexual activity, multiple sexual partners, unmarried marital status, and sexual activity associated with illicit drug use and previous infection are also well-documented risk factors for gonorrhea. Annual screening for gonorrhea is recommended for high-risk men and women. Factors that increase risk include age younger than 25 years, having previous gonorrhea infection or other STDs, having new or multiple sex partners, using condoms inconsistently, working in the commercial sex industry, using drugs, or living in communities with a high prevalence of disease.

Clinical Manifestations

The term *gonorrhea* is often assumed to refer to an illness characterized by urethral discharge in men or vaginal discharge in women. Infections caused by *N. gonorrhoeae* are in fact typically limited to superficial mucosal surfaces lined by columnar or cuboidal, nonkeratinized epithelial cells, such as those sites noted above. Infection of these mucosal surfaces is usually accompanied by a marked inflammatory response that results in the production of copious, purulent discharge. However, *N. gonorrhoeae* can infect several anatomic sites, including the cervix, urethra, rectum, oropharynx, and conjunctiva, and is associated with a wide spectrum of disease. An individual with gonorrhea may have no symptoms at all, may have localized symptomatic disease, may have localized complicated disease, or may be very ill with disseminated infection and bacteremia. Of men and women who report sexual exposure to partners with gonorrhea, urethral infection in men is asymptomatic up to 50% of the time and cervical infection in these women is asymptomatic up to 70% of the time. Pharyngeal and rectal infections secondary to gonorrhea are typically asymptomatic in up to 90% of cases. Individuals who develop disseminated gonococcal infection (DGI) commonly have asymptomatic mucosal infections, detected only by diagnostic testing. It is unknown whether strains that cause DGI are more likely to cause asymptomatic mucosal infection or if individuals who lack symptoms simply do not seek medical treatment before the infection eventually spreads.

Gonococcal infections in women

The most common form of uncomplicated gonorrhea in women is cervicitis. The vagina is usually not infected because it is lined by a squamous epithelium. The urethra is colonized in 70–90% of infected women. In women who have undergone a hysterectomy, the urethra is the most common site of infection. The Skene's glands (paraurethral glands) and Bartholin glands are also commonly infected in the setting of endocervical infection with *N. gonorrhoeae*. Symptoms typically appear within 10 days of infection, although the incubation period can vary. The symptoms associated with endocervical infection may include vaginal discharge, genital itching, intermenstrual bleeding, unusually heavy menstrual bleeding, or painful urination. An infected woman may have all, none, or any combination of these symptoms; and symptoms may range from mild to severe. Physical examination may be normal but may reveal a purulent discharge from the cervix, redness and swelling of the cervix, and easily induced cervical bleeding. These signs and symptoms are not specific for gonorrhea, however. Thus, evaluation of sexually active women suspected of having gonorrhea must include testing for *C. trachomatis*, *Candida albicans*, *Trichomonas vaginalis*, bacterial vaginosis, and other STDs.

PID is the most serious complication of *N. gonorrhoeae* infection in women, affecting approximately 10–20% of all women with acute infection. Gonococcal PID results from the spread of the organism into the upper genital tract. Symptoms of PID can include fever, unilateral or bilateral lower abdominal pain, pain associated with sexual intercourse, abnormal menses or intermenstrual bleeding, or other complaints associated with an intraabdominal infection. These symptoms may be severe or mild. Findings on physical exam include abdominal or uterine tenderness, adnexal tenderness, cervical motion tenderness, and occasionally an adnexal mass or fullness that may be suggestive of a tubo-ovarian abscess. PID can be caused by a number of other infectious agents,

and treatment of PID thus includes broad-spectrum antibiotics targeting chlamydia, gonorrhea, and sometimes, anaerobic bacteria. PID is a significant complication not only because of the acute manifestations but also because of the long-term sequelae, including infertility, ectopic pregnancy, and chronic pelvic pain. Approximately 10% of women will become infertile after a single episode of PID. For those women who remain fertile, there is a tenfold increase in the risk of ectopic pregnancy. The manifestations of gonorrhea in pregnant women are similar to those in nonpregnant women, although PID is less common. Pregnant women with genital gonorrhea are at significant risk for spontaneous abortion, premature rupture of membranes, premature delivery, and acute chorioamnionitis, as well as for transmitting gonorrhea to their newborns during delivery. Neonates infected with gonorrhea can suffer eye and pharyngeal involvement, as well as other complications. Consequently, all newborn infants' conjunctivae are treated prophylactically with topical antibiotics to prevent ocular infection.

Gonococcal infections in men

For symptomatic men, the most common manifestation of infection with *N. gonorrhoeae* is urethritis. Infected men often develop a urethral discharge that can range from scant and clear to copious and purulent. Acute infection is usually accompanied by dysuria (painful urination), which develops after the onset of discharge, and may be the sole manifestation. Symptoms typically develop 2–5 days after exposure to an infected sexual partner, although there can be a delay of over 2 weeks. Untreated acute infection can result in complications, including acute epididymitis, acute and chronic prostatitis, and rarely cellulitis, penile lymphangitis, or periurethral abscess. The most common complication is acute epididymitis, which presents with gradually worsening unilateral scrotal pain. Examination of a man with epididymitis may reveal previously unnoticed urethral discharge as well as tenderness and swelling of the posterior of the scrotum. In young men under the age of 40 years, coinfection with other STDs, particularly *C. trachomatis*, is as common as it is for their female counterparts. Thus, treatment of gonococcal urethritis and associated complications should target both organisms. In older men, structural abnormalities of the urinary tract predispose to infections caused by Gram-negative bacteria and other urinary tract organisms.

Other gonococcal infections

Anorectal gonorrhea is uncommon in heterosexual men, but it is seen more frequently in homosexual men and in approximately 35–50% of women with gonococcal infection of the endocervix. Receptive anal intercourse is the principal mode of transmission in homosexual men, whereas rectal infections in women more commonly arise from local contamination by cervicovaginal secretions. Most men and women with anorectal gonorrhea are asymptomatic; however, some will develop symptoms of proctitis, including severe rectal pain, tenesmus, rectal discharge, and constipation. Other symptoms may include anal itching, painless purulent discharge, or a small amount of rectal bleeding. The vast majority of gonococcal pharyngeal infections are asymptomatic; however, these cases may rarely be associated with acute pharyngitis, tonsillitis, fever, or lymph node enlargement in the neck. Extragenital infections may occur in the absence of genital infections. Several recent studies suggest that a majority of gonococcal infections would be missed in MSM not screened at extragenital sites. In women, up to 30% of gonococcal infections would be missed if extragenital screening were not performed (but the number needed to screen to detect a case of extragenital gonorrhea is much higher in women than in MSM). Consequently, the CDC recommends that all sexually active MSM be screened at all sites of exposure. *N. gonorrhoeae* infections of the eye occur most commonly in newborns, termed ophthalmia neonatorum, as a result of exposure to infected maternal secretions during delivery. These infections can result in corneal scarring or perforation of the cornea, and thus prompt diagnosis and treatment are crucial. Fortunately, the use of silver nitrate or erythromycin eye drops at birth is effective in preventing gonococcal ophthalmia neonatorum. Adults can also acquire gonococcal ocular infection through auto-inoculation, and develop keratoconjunctivitis as a result.

DGI

DGI occurs in approximately 1–2% of individuals with untreated gonorrhea as a result of the spread of the organism from typically asymptomatic mucosal infections of the pharynx, cervix, urethra, or rectum into the bloodstream. DGI is more common in women than in men, and bacteremia probably begins 7–30 days after initial infection. DGI is often referred to as an arthritis/dermatitis syndrome, given the usual findings of an asymmetric polyarthritis and associated rash. The joint manifestations in DGI may begin with painful joints, which progress to frank arthritis later in the course of disease. Approximately 30–40% of patients with DGI will present with overt arthritis, usually involving the wrist, metacarpophalangeal, ankle, or knee joints, although any joint may be involved. Joint fluid cultures are often negative except when the fluid has a high white blood cell concentration, usually more than 40 000 white blood cells per cubic millimeter. Overall, only 20–30% of joint fluid cultures from patients with DGI will be positive for the organism. The rash associated with DGI is composed of a small number (fewer than 30) of tender, necrotic pustules on a reddened base, usually located on the distal extremities. The skin lesions may, however, appear as macules, papules, petechiae, bullae, or ecchymoses. Despite the fact that DGI represents a bloodstream infection, patients often do not clinically appear particularly ill. Blood cultures, like joint fluid cultures, are only positive in 20–30% of patients with DGI. As previously noted, the mucosal infections in DGI are usually asymptomatic. Thus, the diagnosis of DGI can be difficult to make. When DGI is suspected, it is very important to test all potential mucosal sites, in addition to blood and joint fluid, for *N. gonorrhoeae*, to help confirm the diagnosis. Rarely, DGI can be further complicated by seeding of the meninges or the heart valves, resulting in potentially life-threatening gonococcal meningitis or endocarditis. DGI can also occur in newborns of infected mothers, when exposed to secretions during vaginal delivery. The illness in neonates can be similar to that in adults, with associated meningitis and arthritis. Gonococcal disease in newborns usually manifests 2–5 days after birth.

Diagnosis

Gram stain and culture are inexpensive methods for the detection of *N. gonorrhoeae*, although newer nonculture techniques, particularly NAATs, are proving to be more convenient and more sensitive. Specimens for both Gram stain and culture must be obtained directly from the urethra or cervix with a special swab. For the detection of gonococcal urethritis in symptomatic men, a Gram stain of an appropriately obtained specimen can provide rapid and accurate results. A Gram stain is considered positive for gonococcus if Gram-negative diplococci are seen within polymorphonuclear leukocytes. Gram stain results are more difficult to interpret in women and on rectal and pharyngeal specimens because of the presence of other Gram-negative organisms. Isolation of *N. gonorrhoeae* by culture is necessary for antibiotic resistance testing. Optimal recovery of *N. gonorrhoeae* requires the direct inoculation of the specimen onto selective media, followed by incubation at 35–37 °C under 5–7% carbon dioxide. The most commonly used selective media include modified Thayer-Martin, Martin-Lewis, and New York City media. These media contain antimicrobial substances to suppress the overgrowth of other microorganisms that can obscure the presence of the small colonies typical of *N. gonorrhoeae*. *N. gonorrhoeae* can survive for 5–7 h in special transport media, permitting clinics without the necessary laboratory capabilities to transport clinical specimens to nearby laboratories better able to process the specimens appropriately.

Nonculture techniques detect gonococcal antigens, gonococcal enzyme activity, or gonococcal genetic material. One test uses a single-stranded DNA probe to detect gonococcal ribosomal RNA, and it is fairly sensitive and highly specific for gonorrhea. DNA probes have been approved by the FDA for the diagnosis of *N. gonorrhoeae* from urethral and endocervical specimens. In most studies, compared with culture, DNA probes have similar accuracy. NAATs are the most commonly used diagnostic tests. They amplify *N. gonorrhoeae* DNA or RNA using polymerase chain reaction (PCR), transcription-mediated amplification (TMA), or strand displacement amplification. These tests tend to be more sensitive and can provide results more rapidly, within hours, compared with culture, but they are more expensive. Another advantage of NAATs is that they can be performed on different specimen types. In women, the CDC recommends that NAATs be run preferentially on vaginal swabs (either clinician-collected or self-collected). Urine, endocervical, and liquid Pap medium are acceptable alternate specimens for NAATs. In men, the CDC recommends that NAATs be run preferentially on first-catch urine. A urethral swab is an acceptable alternate specimen. Despite not being FDA-cleared for diagnosing rectal or pharyngeal infections, the CDC currently recommends NAATs as the preferred diagnostic modality for these infections because of their enhanced sensitivity compared with culture. Most commercial laboratories have conducted in-house validation studies on NAATs using extragenital specimens. Hence, these tests are routinely available. Currently, there are no acceptable serologic tests for the diagnosis of gonorrhea.

Treatment

For several decades, penicillin was the drug of choice for the treatment of gonococcal infections. By the late 1980s, however, penicillin resistance had become widespread, and penicillin was no longer a reliable choice for effective therapy. Antibiotic resistance may be plasmid-mediated or chromosomally mediated, and some strains of *N. gonorrhoeae* have become resistant to most antibiotics. In 1990, the CDC initiated the Gonococcal Isolate Surveillance Project to monitor trends in antibiotic resistance among gonococcal isolates. Between 1990 and 2001, the rate of fluoroquinolone-resistant isolates remained less than 1%. Subsequently, the rate of resistance increased steadily each year, and by 2007, the CDC no longer recommended the use of fluoroquinolones for the treatment of gonococcal infections and associated complications including PID. As a result, only one class of drugs, cephalosporins, remained available for the treatment of gonorrhea. At that time, the CDC recommended the use of intramuscular ceftriaxone or oral cefixime to treat uncomplicated gonorrhea. Within a short period of time, the MICs to cefixime were noted to be increasing. The CDC increased the recommended dosage of ceftriaxone. Then, in 2012, the CDC recommended that a combination of two drugs be used to treat gonorrhea— even if concomitant infection with chlamydia were ruled out. The only first-line regimen currently recommended by the CDC is the combination of intramuscular ceftriaxone with either oral azithromycin or doxycycline. Cefixime, in combination with either azithromycin or doxycycline is an alternate regimen that should not be used unless the preferred regimen is not feasible. For those with a cephalosporin allergy, the only recommended alternate option is high-dose azithromycin. If alternate regimens are used to treat gonorrhea, the CDC recommends that a test of cure be performed one to two weeks after therapy to ensure eradication of the infection. Specific treatment recommendations have been published by the CDC most recently in the *Sexually Transmitted Diseases Treatment Guidelines, 2010* (Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines, 2010. MMWR 2010;59(No. RR-12) and can also be found at the CDC's website, <http://www.cdc.gov/>. The most common cause for treatment failure is repeated exposure to an untreated sexual partner. Given the prevalence of asymptomatic gonorrhea, treatment of all sexual partners from within the previous 60 days is recommended, regardless of whether they have symptoms suggestive of infection. If the patient's most recent sexual encounter was more than 60 days before the onset of symptoms or diagnosis, then the patient's most recent partner should be treated. All persons treated for gonorrhea should be re-tested in 3 months because reinfection rates are very high.

Organism and Pathogenesis

N. gonorrhoeae belongs to the family Neisseriaceae, which includes several nonpathogenic species and the well-recognized pathogen *Neisseria meningitidis*. *N. gonorrhoeae* is a fastidious Gram-negative diplococcus, 0.6–1.0 µm in diameter, with complex growth requirements described earlier. *In vivo*, gonococci grow under relatively anaerobic conditions and are capable of growing under

strictly anaerobic conditions *in vitro*. *N. gonorrhoeae* produces high levels of catalase and produces an oxidase. Because oxidase production is easy to detect in the laboratory, oxidase-positive Gram-negative diplococci that are obtained from appropriate clinical specimens, and that grow on selective media, are presumed to be *N. gonorrhoeae* in most cases. *N. gonorrhoeae* can be distinguished from other *Neisseria* species on the basis of sugar fermentation patterns. *N. gonorrhoeae* utilize only glucose, pyruvate, and lactate as their carbon source. Other *Neisseria* species, *Kingella dentrificans*, *Moraxella* species, and *Branhamella catarrhalis* can be mistaken for *N. gonorrhoeae*, particularly given their similar appearance on Gram stain. Such errors can have serious repercussions for patients and their health care providers, given the social and medicolegal implications of being diagnosed with an STD.

The structure, molecular biology, and pathogenesis of *N. gonorrhoeae* have been studied extensively, yet many processes remain elusive. The cell wall is made up of pili, a capsule, several characteristic outer membrane proteins referred to as protein I, Opa protein (opacity-related proteins or protein II), protein III (Rmp), iron-regulating proteins, lipooligosaccharides (LOS), H.8 (Lip), and other components that can vary with growth conditions. The pili are hair-like filamentous appendages that extend from the cell surface. Pili are an important virulence factor. Pili, in concert with protein II, enable gonococci to attach to the microvilli of host nonciliated columnar epithelial cells. Protein I is the most prominent outer membrane protein and functions as a porin, providing a hydrophilic channel through the outer membrane. Protein I triggers endocytosis of gonococci by the host mucosal cell. Following endocytosis, the membrane of the mucosal cell retracts around the organism, forming a membrane-bound vacuole, which is transported to the base of the cell, where gonococci are subsequently released into the subepithelial tissue. Unlike most of the other outer membrane proteins, protein I is always expressed, and it is useful in identifying individual strains of gonococci because each strain produces a single antigenically stable protein I. Protein I also appears to inhibit neutrophil function, and thus may limit the ability of the host to respond to infection.

In addition to enhancing the adhesion of gonococci to mucosal cells, Opa/protein II appears to mediate infection by enhancing gonococcal cell-to-cell adhesion, which may result in a more infectious unit. It specifically appears to enhance adhesion to conjunctival cells, epithelial cells, and neutrophils. Protein III (Rmp) appears to be able to block bactericidal antibodies produced by the host directed at other surface proteins acting as antigens, specifically protein I and LOS. LOS is similar to the lipopolysaccharide component characteristic of the cell wall of all Gram-negative bacteria, except that it lacks long, hydrophilic, neutral polysaccharides. LOS appears to mediate most of the damage to host tissues. LOS is the primary target of host antibodies, and it regulates complement activation on the cell surface of gonococci in addition to prompting the release of enzymes, such as proteases and phospholipases. Evidence suggests that gonococcal LOS stimulates the production of tumor necrosis factor (TNF) in fallopian tube organ cultures, and in other settings, the inhibition of TNF has been shown to limit tissue damage. LOS also appears to be capable of molecular mimicry as demonstrated by the similarity of terminal LOS to host glycolipids, and thus hinders the ability of the host to mount an effective host immune response. Pili, protein II, and LOS also exhibit extensive intra- and interstrain antigenic variations, as well as phase variation in pili and protein II expressions. Such variation likely represents a mechanism by which gonococci can escape the host immune response.

Chlamydia

Epidemiology

Chlamydia is the leading bacterial cause of STDs worldwide. Chlamydia, caused by *C. trachomatis*, is the most commonly reported STD in the United States. There are an estimated 2.9 million new cases in the United States each year, at an estimated cost of \$2.4 billion, with an estimated \$10 billion annually associated with the treatment of PID. Chlamydia became a reportable disease in several states in 1986, and for years thereafter the number of reported cases increased steadily, likely as a result of improved diagnostic techniques, screening practices, and reporting in more states. Chlamydia became the most common reportable disease in the United States in 1995, when 477 638 cases were reported. In 2012 that number had risen to 1 422 976. As with other STDs, these numbers most likely underestimate the actual burden of disease as data on the true incidence and prevalence of chlamydia are limited by a number of factors. Chlamydial infections are often asymptomatic, and in screening study of women attending a family planning clinic, 70% of the women found to have genital infections secondary to chlamydia had neither clinical findings nor symptoms of infection. Thus, a significant number of cases likely go unrecognized by the patient or health care provider. When symptoms are present, individuals are often treated empirically without diagnostic confirmation, and thus these cases of chlamydia are never reported.

Several studies in a variety of settings, utilizing different diagnostic screening strategies, have provided additional estimates of the prevalence of genital chlamydial infections in the United States. Approximately 3–5% of asymptomatic men and women seen in general medical settings are infected with chlamydia, whereas women and men screened in STD clinics have a prevalence of 15–20%. More recent studies using highly sensitive diagnostic assays reported even higher prevalence data. In one study, Burstein and colleagues demonstrated that the prevalence of chlamydial genital infections among adolescent females screened in family planning, STD, and school-based clinics in Baltimore, Maryland, was 29.1%. The majority of infected girls were asymptomatic. In a study in which 13 204 new female army recruits were screened, the prevalence was 9.2%. Interestingly, there was wide geographic variation in the prevalence of chlamydial infection according to the state of origin of the recruit, ranging from more than 15% in women from some southern states to 5% in other states, including Washington and Oregon, where aggressive public health initiatives have been in place since the late 1980s, aimed at reducing the number of chlamydial infections. In a similar study of 2245 male army recruits, the prevalence of chlamydial urethritis was 5.3% overall, with similar geographic variation by state. Of the men infected with chlamydia, over 85% were asymptomatic.

Specific risk factors for chlamydial infection have been consistently identified in these studies. The single most important risk factor for chlamydial infections in women is young age. Among women, the 20–24 year age group had a rate of 3695.5 per 100 000 while the 15–19 year group had a rate of 3291.5 per 100 000. The respective rates in men were 1350.4 and 744.8 per 1 000 000, respectively. Studies of reinfection have shown that up to 20–30% of female adolescents had evidence of another chlamydial infection within 6 months of the initial infection, and it is recommended that women be retested for chlamydia 3 months after treatment. Other risk factors associated with chlamydial infection mirror those associated with other STDs and include multiple sex partners, a recent new sex partner, inconsistent condom use, and nonwhite race. Although chlamydia is common among all races in the United States, African American women are disproportionately affected. In 2012, according to the CDC, the rate of reported chlamydia infections per 100 000 African Americans females was 1229.4, more than 7 times that of whites (179.6 per 100 000) and more than twice that of Hispanic females (380.3 per 100 000). Another important risk factor for chlamydia is the diagnosis of gonorrhea. The CDC recommends annual screening of all sexually active women under the age of 26 years, whether or not symptoms or other risk factors appear to be present. Data from a study in a managed care setting showed that chlamydia screening and treatment can reduce the incidence of PID by more than 50%. Increased screening and treatment efforts would also most likely reduce other adverse health consequences such as infertility.

Chlamydia is also a problem for pregnant women and their newborns. Prevalence studies in pregnant women using relatively insensitive screening techniques yielded prevalence rates of 5–7%, although prevalence rates of 21–25% have been identified in inner-city and Native American populations. Of infants born to untreated infected mothers, approximately 60–70% can become infected with chlamydia, a significant proportion of which go on to develop pneumonia and ocular complications (chlamydial ‘ophthalmia neonatorum’) as a result. Given the results of these studies, some areas of the United States have instituted broad-based screening and treatment programs, and the prevalence of chlamydial infections in these areas has declined dramatically. In the Pacific Northwest of the United States, screening for chlamydia in patients attending family planning clinics began in 1988 and in STD clinics in 1993. The prevalence of chlamydia in this region declined from 10–12% in the late 1980s to 4–5% in 1995. One challenge to these efforts is the relatively long incubation period of chlamydia of 1–3 weeks. Infected individuals may not develop symptoms for a prolonged period of time, if at all, and thus may remain sexually active while infectious. The efficiency with which chlamydia is transmitted between sexual partners is not well understood. Studies evaluating the sexual partners of infected individuals demonstrated an infection rate of 85% among female contacts of men with chlamydial urethritis. Traditionally, researchers suspected that men were more likely to transmit chlamydia to women than the other way round, but more recent data from studies using highly sensitive diagnostic techniques suggest that transmission may be equal in both directions.

From a global perspective, however, perhaps the greatest burden of disease caused by *C. trachomatis* is trachoma, which affects the inner upper eyelid and is one of the most common infectious causes of blindness. According to the WHO, in some parts of the developing world 90% of the population is infected. The disease is especially common in poorer, rural communities. Here, the infection is not sexually transmitted but tends to be a communicable disease among family members and is exacerbated by limited access to water and adequate personal hygiene.

Clinical Manifestations

There are several subtypes of *C. trachomatis*, the trachoma and lymphogranuloma venereum (LGV) subtypes being the only human pathogens. LGV is caused by *C. trachomatis* serovars L₁, L₂, or L₃, and are transmitted through sexual contact. Infection with one of these serovars is typically associated with painful unilateral lymphadenopathy and sometimes ulceration and abscess formation. Rectal infections in MSM can result in severe proctocolitis with chronic sequelae if untreated, including colorectal fistulas and strictures. In recent years a resurgence of LGV proctitis has been observed in western Europe and the U.S. associated with LGV serovar L₂.

Genital infections caused by the D-K serovars of *C. trachomatis* have many of the same characteristics as those caused by *N. gonorrhoeae*. Both organisms preferentially infect columnar epithelial cells and do not appear to be capable of growth in squamous cells. Thus, like gonorrhea, chlamydia infects the urethra, with extension to the epididymis and possibly the prostate gland in men, the squamocolumnar junction of the endocervix in women, with the potential for spreading to the endometrium and upper genital tract, and the rectum. *C. trachomatis* can also cause conjunctivitis. In contrast to gonorrhea, however, chlamydial infections generally have a longer incubation time, are associated with a less robust inflammatory response, and are more likely to be asymptomatic. Unlike gonorrhea, chlamydia does not disseminate to cause a systemic infection like DGI. Unfortunately, there are no unique signs or symptoms to help make the diagnosis of *C. trachomatis* infection of the genital tract. The associated symptoms and physical findings, if present at all, can also result from other infections or complications, and therefore one has to have a high index of suspicion to diagnose a chlamydial infection.

Chlamydial infections in women

In women, *C. trachomatis* most commonly infects the cervix, although approximately 50% of infected women will have simultaneous infection of the urethra. Chlamydial infection of the cervix typically results in cervicitis with a mucopurulent discharge, present in only 20–40% of infected women. On examination, there is sometimes visible swelling and easily inducible bleeding in a zone of ectopy, an area with a relative increase in exposed columnar cells at the squamocolumnar junction. As previously noted, however, in studies in which women were screened for chlamydia, 70% or more of infected women did not have any abnormal clinical findings. Women with cervical ectopy have a higher prevalence of chlamydia than those without ectopy. Cervical ectopy is

normally present in 60–80% of sexually active adolescent females, and declines with age. This finding may in part explain the higher prevalence of chlamydia among adolescent females. Oral contraceptives are also associated with cervical ectopy, and this may account for the increased risk of chlamydia, and gonorrhea, for women on oral contraceptives. Chlamydial urethritis has also been well documented in women and is estimated to occur without concomitant cervical infection about 25% of the time. The prevalence of isolated urethral infection increases with age. Chlamydial urethritis may be associated with painful and frequent urination, although the majority of women with urethritis do not have symptoms. Nonetheless, *C. trachomatis*, as well as *N. gonorrhoeae*, should be considered as a possible diagnosis in sexually active women with urinary symptoms if there is evidence of coexisting cervicitis or if other STD risk factors are present.

The most serious form of *C. trachomatis* infection is upper genital tract disease. Approximately 10% of women with cervical chlamydia infection will develop symptomatic PID. There is likely an even larger proportion of infected women who develop asymptomatic upper tract disease. All of these women are at increased risk for infertility and ectopic pregnancy as a result of tubal inflammation and scarring. The clinical manifestations of PID secondary to chlamydia are similar to those of PID caused by gonorrhea, and are discussed more completely in section ‘Gonococcal infections in women’. As with other sites of infection, chlamydial infection of the upper tract is clinically milder and more likely to be asymptomatic than infections caused by gonorrhea or anaerobic bacteria, despite ongoing tubal damage. Like gonorrhea, chlamydia can cause perihepatitis, with or following the development of PID, referred to as the Fitz-Hugh–Curtis syndrome. Women who are infected with chlamydia in the first trimester of pregnancy are at increased risk of postpartum endometritis following vaginal delivery.

Chlamydial infections in men

More common than gonococcal urethritis is the entity known as nongonococcal urethritis (NGU). A diagnosis of NGU is made when *N. gonorrhoeae* cannot be identified in urethral specimens from a man with urethritis. *C. trachomatis* is believed to be the causative organism in 25–35% of cases of NGU, with a lower prevalence among older men. Other organisms include *Mycoplasma genitalium*, *T. vaginalis*, and herpes simplex virus. NGU is often characterized by the presence of inflammatory cells in the urine and a urethral discharge that is usually less purulent and relatively scant as compared with the urethral discharge associated with gonorrhea. Infected men may experience painful or frequent urination. However, the symptoms are variable enough that one cannot reliably distinguish NGU from gonococcal urethritis clinically. If a Gram stain of the urethral specimen shows a large number of inflammatory cells (specifically polymorphonuclear cells) without intracellular diplococci, then a presumptive diagnosis of NGU is made. A diagnosis of chlamydial urethritis requires specific diagnostic testing.

Chlamydial infections of the lower genital tract in men may also become complicated. *C. trachomatis* is the most common cause of epididymitis in sexually active young men, accounting for approximately 70% of cases. Epididymitis results from the spread of an untreated chlamydial urethral infection to the upper genital tract, and it is characterized by progressive unilateral scrotal pain and swelling. Chlamydial urethritis has also been associated with the subsequent development of Reiter’s syndrome. Reiter’s syndrome consists of urethritis, conjunctivitis, arthritis, and characteristic skin lesions. Some studies have found that 80% of men with Reiter’s syndrome have evidence of prior or ongoing chlamydial infection. This syndrome is more common in men with the HLA-B27 haplotype. These patients may also develop arthritis or tenosynovitis, without the other features of Reiter’s syndrome, in association with infection with *C. trachomatis*, and usually improve following treatment for chlamydia.

Other chlamydial infections in adults

Both men and women can develop proctitis as a result of rectal infection with *C. trachomatis*. Rectal infections are usually asymptomatic, but if proctitis develops patients may experience rectal pain, bleeding, and a mucous discharge. Adults can also develop an acute follicular conjunctivitis as a result of autoinoculation of the eye with infected genital secretions. Conjunctivitis can develop within 1–3 weeks and does not typically result in permanent damage or vision loss.

Chlamydial infections in neonates

Neonates exposed to *C. trachomatis* during vaginal delivery are at risk for developing conjunctivitis and pneumonia. Nasopharyngeal infection is also common. Conjunctivitis develops within 5–21 days and is characterized by copious purulent discharge and redness of the eye. As in adults, it is usually self-limited and does not result in permanent eye damage or vision loss. Pneumonia caused by chlamydia can be life-threatening, however. The incubation period for chlamydial pneumonia in neonates is 2–12 weeks. Infected infants often have a history of conjunctivitis and present with rhinitis, rapid breathing, and a characteristic cough in the absence of fever. There is evidence to suggest that infants who have chlamydial pneumonia frequently go on to develop asthma or obstructive airway disease, even after appropriate treatment of the initial pneumonia.

Diagnosis

Because *C. trachomatis* is an obligate intracellular organism, cell culture has traditionally been the gold standard for the diagnosis of chlamydia. Cyclohexamide-treated McCoy cells are the most commonly used cell culture system. Cell culture is often impractical, however, because of the high level of technical expertise needed, as well as the strict requirements for specimen collection and transport, and high cost. Samples of discharge or secretions containing only inflammatory cells are not adequate. Instead, carefully collected samples of cervical or urethral columnar cells are necessary. Specimens must then be refrigerated in special transport media and inoculated onto cell culture plates within 24 h. When done correctly, cell culture has a sensitivity of

80%. Because of these limitations, several nonculture techniques have been developed, including a direct fluorescent antibody (DFA) test, enzyme immunoassay (EIA), and direct DNA probes. Although these tests may be relatively inexpensive and more convenient in some settings, they still require careful specimen collection and must be processed by an experienced technician. The DFA test is slightly more sensitive than the EIA when performed properly, with a sensitivity of 80–85% and a specificity of 99% relative to culture. The EIA is only 60–80% sensitive when compared with culture. The performance of direct DNA probes is comparable with that of DFA.

The development of NAATs to detect amplified chlamydial DNA or RNA has markedly improved diagnosis. These techniques utilize PCR or TMA. Perhaps the greatest benefit of NAATs is that they can be performed on vaginal, cervical, first-catch urine, urethral, rectal, and liquid-based Pap samples. The preferred specimens are similar to those for gonorrhea testing (see above). NAATs are highly sensitive and 99–100% specific. The CDC recommends rectal screening for *C. trachomatis* in all MSM who report rectal exposures, but not pharyngeal testing because the prevalence is low. NAATs testing will detect both D-K and L1-L3 serotypes of *C. trachomatis* but will not distinguish the two serotypes. Additional testing (multiplex PCR or sequencing) must be obtained to reliably distinguish between D-K and LGV serotypes. It is important to distinguish between these two serotypes because treatment regimens differ. Serologic tests are not appropriate in the diagnosis of uncomplicated genital tract infections, primarily because of the high prevalence of antibodies to *C. trachomatis* in sexually active adults. High antibody titers may be seen in patients with complicated upper tract disease, and thus support the diagnosis of chlamydial PID or epididymitis. However, sexually active patients with PID or epididymitis should be treated for chlamydia regardless of the results of serologic testing. Serologic testing may be used to diagnose LGV, but these tests are not standardized for LGV proctitis.

Treatment

Macrolides, tetracyclines, and quinolones, with the exception of ciprofloxacin, are all effective against chlamydia. There has not been any convincing evidence of emerging antibiotic resistance, as has been the case for gonorrhea. Currently, the treatment of choice for uncomplicated chlamydial infections of the lower genital tract is 1 g of oral azithromycin. Alternatively, a 1-week course of doxycycline can be used. Although azithromycin is more expensive than doxycycline, cost-effectiveness analyses demonstrate that this treatment option is a cost-effective choice because of the improvement in compliance with single-dose therapy. Infected patients and their partners should abstain from sexual activity until they have completed a course of antibiotic therapy, to prevent the transmission of chlamydia before the infection has been indicated. If single-dose therapy is given, individuals should abstain for 7 days following treatment, and all women treated for chlamydia should be rescreened 3–4 months after therapy because of the high prevalence of *C. trachomatis* infections among women with a history of recent infection.

Because tetracyclines and quinolones are not acceptable for use in pregnant women or infants, azithromycin or erythromycin should be used. The effectiveness of erythromycin may be reduced compared with azithromycin due to compliance issues, and therefore patients treated with erythromycin should be retested for chlamydia 2 weeks after the completion of therapy (or 3 weeks if using an amplification test). Conjunctivitis should be treated with oral antibiotics, not topical therapy, because of the risk of infection at other sites. The treatment of PID should routinely include antibiotics effective against chlamydia. All sexual partners within the previous 60 days should also be treated for chlamydia and gonorrhea in a timely manner. If the patient's last sexual encounter was more than 60 days before the onset of symptoms or diagnosis, then the patient's most recent partner should be treated. Specific treatment recommendations have been published by the CDC most recently in the *Sexually Transmitted Diseases Treatment Guidelines, 2010* (Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines, 2010. MMWR 2010;59(No. RR-12) and can also be found at the CDC's website, <http://www.cdc.gov/>.

Organism and Pathogenesis

C. trachomatis is one of four species within the genus *Chlamydia*. Among the others, *C. pneumoniae* and *C. psittaci* are also human pathogens. The fourth, *C. pecorum*, is a pathogen of mammals but is not believed to cause disease in humans. A detailed review of *Chlamydia* species and their pathogenesis is found in a related article.

Syphilis

Epidemiology

Syphilis is a complex and fascinating disease, caused by infection with the bacterium *Treponema pallidum*. The disease is systemic, potentially affecting nearly every organ in the body and so mimics many other disease processes. Syphilis is characterized by several different stages, including primary, secondary, tertiary, and latent stages, and it can persist for decades if untreated. Syphilis is distributed worldwide and is particularly a problem in the developing world, where it is the leading cause of genital ulcer disease. Syphilis is highly infectious, but easily curable if treated during its early stages. Before the development of penicillin in the 1940s, syphilis was a big public health problem in the United States. At the beginning of World War II, the US Public Health Service estimated that approximately 2.5% of all Americans were infected with syphilis. With the advent of penicillin, however, the prevalence of primary and secondary (P&S) cases declined by about 93%. Fortunately, penicillin remains fully effective against syphilis, with no evidence of the emergence of penicillin resistance.

Nonetheless, syphilis remains a significant public health concern. According to the CDC, beginning in the mid-1980s there was a marked and progressive resurgence of P&S syphilis, the most infectious stages of the disease, in the United States that peaked in 1990, with a total of 55 132 reported cases of P&S syphilis, representing a 20.2% increase over the previous year. The reasons for these trends are unclear. Of concern was the dramatic increase in cocaine use in the United States during the mid- to late 1980s. Cocaine use has been associated with high-risk sexual behaviors. Also of concern have been declines in the resources allocated for public health programs involved in the control of syphilis over the previous two decades. During the 1980s, the majority of cases were initially observed in MSM, and subsequently in intravenous drug-using individuals. In the 1980s, more than 40% of infected men reported other men as their sexual contacts. With the onset of the AIDS epidemic and the associated changes observed in sexual behavior among MSM, the proportion of syphilis cases attributable to this segment of the population declined dramatically. Subsequently, mirroring trends in the HIV epidemic, a growing proportion of syphilis cases were seen in inner-city, heterosexual, drug-using populations. Throughout the 1990s, however, there was a steady decline in reported cases of P&S syphilis in the United States, reaching an all-time low in 2000. Since then, however, there has been a resurgence of cases such that between 2000 and 2013, there was a doubling of the number of cases of primary and secondary syphilis. In 2013, 91% of the cases were diagnosed in men—83% among MSM. Estimates suggest that over half of all men diagnosed with primary and secondary syphilis are co-infected with HIV. Compared to a rate of 9.8 cases per 100 000 men, the rates in women are 0.9 per 100,000, a stable rate after an increase noted between 2005 and 2008. The trend among men, particularly MSM, is troubling, especially given that syphilis, like many other STDs, facilitates the spread of HIV by increasing the likelihood of transmission of the virus between individuals during a sexual encounter. It is recommended that all high-risk groups be screened for syphilis on a routine basis: at least annually for HIV-infected persons and sexually active MSM, and every 3–6 months for higher-risk MSM (e.g. those who report sexual encounters with anonymous sex partners or those who use drugs in conjunction with sex).

As observed with many other STDs, there remain marked discrepancies in the proportion of cases among different racial or ethnic groups. According to the CDC, in 2012 the rate of P&S syphilis among African Americans was 16.4 per 100 000, 6 times that among whites; however, this marks a significant decline from 1999 when the rate among African Americans was 29 times that of white Americans. It is important to recognize though that although this change is a result of a decline in rates among African Americans, it also reflects a significant increase in rates of P&S syphilis among white men. Biases in reporting explain some of the discrepancies in rates among different racial or ethnic groups, but cannot explain them completely. Other more fundamental risk factors for STDs that are also associated with race or ethnicity, such as socioeconomic status, access to quality health care and health education, and others, may also play an important role. Interestingly, syphilis rates do not follow the same age distribution as many other STDs, with the highest numbers of cases among women 20–24 years of age, and among men 20–29 years of age. In 2006, the highest rates among men had been in the 35–39 year age group.

Clinical Manifestations

Syphilis is unique among STDs in its tendency to spread throughout the body via the bloodstream, resulting in the involvement of multiple distant organs, including the central nervous system, bones, arteries, skin, and other sites. Because it is a systemic disease, with sometimes nonspecific signs and symptoms, syphilis can mimic many other disease processes, and patients may be easily misdiagnosed if syphilis is not considered and ruled out by appropriate diagnostic testing. Transmission usually occurs as a result of sexual contact with an infected individual possessing the mucosal lesions typical of P&S syphilis. Syphilis can also be transmitted via contact with infectious lesions seen in the mouth or on the skin in secondary syphilis, or it may be transmitted transplacentally from the mother to the fetus during any stage of the infection, resulting in congenital syphilis. Infected mothers can also transmit syphilis to their newborns through breast-feeding.

T. pallidum begins to multiply at its site of entry, and after an incubation period of 10–90 days, a papule appears at the infected site. The papule eventually converts into the painless superficial ulcer, known as a chancre, characteristic of primary syphilis. Chancres are highly contagious lesions, harboring a high concentration of *T. pallidum*. During this period, infected individuals often develop local lymph node enlargement, but often this sign goes completely unnoticed. After a period of 2–6 weeks, the chancre usually heals spontaneously. Subsequent spread via the bloodstream and multiplication of the organism in other organs results in findings characteristic of secondary syphilis. The signs and symptoms of secondary syphilis usually do not appear until after a 2–24-week period after the resolution of the primary stage, during which the infected individual may be completely asymptomatic. Individuals with secondary syphilis typically develop a rash but often experience other symptoms, such as low-grade fever, malaise, headache, sore throat, generalized lymph node enlargement, and muscle aches. Patients may also develop bone inflammation and hepatitis, both of which are usually asymptomatic. The rash associated with secondary syphilis usually begins with a mild, transient macular rash, which often goes unnoticed. This quickly evolves into an itchy, diffuse, symmetric, raised rash, which involves the entire trunk and extremities, classically including the palms of the hands and the soles of the feet. Other typical lesions, known as condylomata lata, are large, raised white or grayish patches that occur in warm, moist areas, such as the mouth, vagina, or rectum. These skin lesions contain a high concentration of organisms and are highly contagious. Hair loss as well as changes in skin pigmentation of the skin can occur. As seen in primary syphilis, the signs and symptoms of secondary syphilis usually resolve spontaneously after a 2–6-week period, even without treatment.

About 25% of individuals with P&S syphilis may experience multiple relapses of the secondary stage, usually within the first year of infection. After the secondary stage, untreated patients with P&S syphilis become asymptomatic and enter a stage referred to as latent syphilis, for which there are no signs or symptoms at all, and a diagnosis of syphilis can only be made by serologic screening.

Latent syphilis can persist for decades. This stage is arbitrarily divided into early-latent and late-latent stages. By definition, patients with early-latent syphilis are asymptomatic and have been infected for less than 1 year, based on previously negative serologic tests. Those with late-latent syphilis are asymptomatic and have been infected for more than 1 year. The term 'early syphilis' refers to those individuals who, within the preceding year, had a documented seroconversion, unequivocal symptoms of P&S, or a sex partner with documented primary, secondary, or early-latent syphilis. Individuals with early syphilis are believed to be infectious and can thus transmit syphilis to their partners during the primary, secondary, and early-latent stages. If the duration of latent syphilis infection cannot be documented for certain, then patients are assumed to have late-latent syphilis for the purposes of treatment.

One-half of patients who develop latent syphilis will continue to have serologic evidence of infection but will never develop late complications of the disease. The other half may remain asymptomatic for decades but will ultimately develop late manifestations of syphilis if untreated. Individuals with late-latent syphilis are immune to reinfection with *T. pallidum*. This latter group of individuals, if untreated, will eventually experience disease progression and develop what is referred to as tertiary syphilis. Individuals with tertiary syphilis may have involvement of their skin, bones, central nervous system, heart, and arteries, as well as other sites. At this stage, syphilis may be characterized by the presence of destructive granulomatous lesions known as gummas. Gummas may be found in the bones and skin, but they may also be found in other organs, including rarely the heart and digestive tract. The pathogenesis of gumma formation is not known, but gummas usually result in extensive damage to surrounding tissues. Tertiary syphilis involvement of the central nervous system and cardiovascular system may also result from direct invasion by the organism, without gumma formation. Cardiovascular involvement is thought to result from the multiplication of the organism in the aorta and proximal coronary arteries. The associated arteritis can lead to severe aortic valve insufficiency, aneurysm formation, and myocardial infarction. The neurologic effects of tertiary syphilis take two forms. Meningovascular syphilis results from the involvement of the meninges, the tissues surrounding the brain. The parenchymatous form affects the brain, referred to as general paresis, and spinal cord, known as tabes dorsalis, directly. The neurologic manifestations of tertiary syphilis may include meningitis, stroke, dementia, cranial nerve deficits, sensory disturbances, and paralysis. Approximately 80% of deaths from syphilis are attributable to cardiovascular involvement and the remaining result from neurologic disease. Fortunately, tertiary syphilis has become extremely rare since the introduction of penicillin.

Congenital syphilis is a potentially devastating disease, resulting from transplacental transmission of syphilis from an infected mother to her fetus. Approximately 50% of infected fetuses are spontaneously aborted or are stillborn. Those that survive to delivery may exhibit a wide range of signs and symptoms of syphilis. Newborns with symptoms before the age of 2 years have early congenital syphilis, and they develop skin lesions, mucous membrane involvement often with copious secretions, bone involvement, severe anemia, and enlargement of the liver and spleen. Children with late congenital syphilis may not have symptoms until after the age of 2 years, at which time they may develop interstitial keratitis with subsequent blindness, tooth deformities, deafness, neurosyphilis, cardiovascular involvement, and skeletal deformities. Pregnant women who receive prenatal care are routinely screened for syphilis given the terrible consequences of infection for the newborn.

Individuals with syphilis and concurrent HIV infection appear to have a similar experience with regard to P&S syphilis, with one notable exception. Numerous case series have documented rapid progression from early syphilis to neurosyphilis in patients infected with both HIV and syphilis. Many of these patients develop early neurosyphilis, characterized by the clinical manifestations of meningitis, cranial nerve deficits, including hearing loss and blindness, and even stroke, often in the context of therapeutic failure with conventional doses of penicillin for P&S syphilis.

Diagnosis

The most sensitive and specific test for the diagnosis of primary syphilis is the identification of the organism on dark-field microscopy, when performed by an experienced observer on an adequate sample of fluid obtained from the surface of a chancre. *T. pallidum* has a characteristic corkscrew appearance on dark-field microscopy, and false-positive results do not occur in experienced hands. Serologic tests can be useful in the diagnosis of primary syphilis, although false-negative results occur 10–20% of the time. The rapid plasma reagin (RPR) and the Venereal Diseases Research Laboratory (VDRL) are referred to as 'nontreponemal tests' because they do not measure antibodies specific to treponemal components. As a result, these assays may occasionally be positive in other disease states and are less specific than treponemal tests. These assays are also more likely than treponemal tests to be negative in primary syphilis. The RPR titer does, however, correlate with disease activity and often becomes negative after adequate treatment, although it may remain positive at a low titer throughout one's life. Thus, even when the diagnosis of syphilis is made by other means, it is useful to obtain an RPR to monitor subsequent disease activity. Tests such as the fluorescent treponemal antibody absorbed or the microhemagglutination assay for antibody to *T. pallidum* are referred to as treponemal tests. These assays are more likely to be positive in primary syphilis than the RPR or VDRL and remain positive for life, but they are not useful in monitoring disease activity. Because these older assays are specific for syphilis, but are more costly and labor intensive, they are not used for screening but rather to confirm a diagnosis of syphilis when an individual has a positive RPR or VDRL. Newly developed treponemal antibody tests, the treponemal enzyme immunoassays (EIA) and the chemoluminescent assay (CIA) are automated tests that are now being used by many laboratories as the initial screening tests for syphilis. If positive, the laboratory automatically obtains a reflex RPR. If the RPR is also positive, clinicians should stage the infection based on history and treat accordingly. If the RPR is negative following a positive initial EIA or CIA, the laboratory should run a second different treponemal test to confirm that the EIA or CIA is a true positive. If the second treponemal test is positive, clinicians must obtain a careful history to determine the next appropriate step. Causes of positive treponemal tests with a negative RPR include old treated syphilis, old untreated syphilis (RPR

titers may become negative over time even in the absence of therapy), or early syphilis (treponemal tests may become positive before the non-treponemal tests in early syphilis).

Secondary syphilis can be diagnosed by dark field examination of material taken from skin lesions of individuals with secondary syphilis. Serologic assays are much more reliable in diagnosing secondary syphilis compared with primary syphilis, however, and are the preferred method of diagnosis in this setting. The RPR is always positive in secondary syphilis, usually with a high titer. The treponemal tests are also always positive in secondary syphilis, and may be used to confirm that a positive RPR is in fact due to syphilis. The RPR is then used to monitor the response to therapy. In rare cases, non-treponemal tests may be falsely negative in secondary syphilis due to the prozone reaction. Dilution of the serum sample is the preferred approach if a prozone reaction is suspected.

Because individuals with latent syphilis are asymptomatic, latent syphilis is usually diagnosed by serological tests. A diagnosis of latent syphilis is easily made if an individual recalls a recent history of a chancre or skin rash for which he or she did not seek medical care and is currently asymptomatic. Unfortunately, most asymptomatic individuals with positive serologies are unable to provide a diagnostic medical history. For public health purposes, these individuals are assumed to have late latent syphilis and are thus treated accordingly. Most local public health departments keep a record of all positive syphilis serologies and attempt to maintain records on treatment and subsequent response to therapy. If a current RPR titer is positive at fourfold lower than previously documented titers (e.g., from 1:16–1:4), then the individual has likely had an appropriate response to prior therapy.

A diagnosis of neurosyphilis is easily made when there are neurologic findings in the setting of positive serologies and abnormal CSF. However, the presence of only two of these three criteria is usually sufficient to mandate treatment for neurosyphilis. The CSF in patients with neurosyphilis may exhibit any combination of the following findings, including an elevated opening pressure, an elevated white blood cell count, an elevated protein concentration, or a positive CSF VDRL. A positive CSF VDRL is diagnostic of neurosyphilis, but this test is not sensitive and is often negative in neurosyphilis. Stroke, dementia, and other neurologic abnormalities are more frequently due to etiologies other than syphilis, but may coincidentally occur in the presence of positive serology. Currently, the CDC recommends that clinicians perform a CSF examination in patients with serological evidence of syphilis and (1) neurological signs or symptoms (2) other signs or symptoms of tertiary syphilis (3) in those whose serological titers do not respond to therapy and in whom reinfection is ruled out. Although HIV-infected persons with syphilis appear to be at greater risk for neurosyphilis, it is not known whether a CSF examination among asymptomatic HIV-infected persons improves long-term outcomes. As such, there are no definitive recommendations that can be made about the utility of CSF examination in these patients. In the absence of gummas, diagnosis of cardiovascular disease from tertiary syphilis is usually made on clinical grounds in the presence of positive serology or a history of syphilis and characteristic findings on angiography. Other forms of tertiary syphilis are usually diagnosed on the basis of the identification of a gumma.

Treatment

Parenteral penicillin G is the preferred treatment for all stages of syphilis. The duration of therapy depends on the stage of syphilis. HIV may alter the response to therapy, and treatment failures have been reported in HIV-infected individuals but the current recommendations recommend similar regimens in HIV-infected and uninfected persons. Specific treatment recommendations have been published by the CDC most recently in the *Sexually Transmitted Diseases Treatment Guidelines, 2010* (Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines, 2010. MMWR 2010;59(No. RR-12) and can also be found at the CDC's website, <http://www.cdc.gov/>.

About one-third of patients with primary syphilis and two-thirds of patients with secondary syphilis develop an unusual reaction to treatment known as the Jarisch–Herxheimer reaction. This reaction typically consists of fever, chills, headache, worsening rash, and even hypotension in severe cases. The onset is usually within the first 4 h after the initiation of therapy, and the reaction resolves within 24 h. It is believed to result from the release of treponemal components, resulting in an endotoxin-like reaction. The Jarisch–Herxheimer reaction may be confused with an allergic reaction to penicillin but is not an indication for discontinuing therapy. Instead, treatment should continue and the patient should be treated with nonsteroidal anti-inflammatory medication, in addition to other supportive measures as indicated. Sexual partners of index cases should be sought out and treated based on the index patient's stage of infection.

Organism and Pathogenesis

T. pallidum is one of several treponemal species associated with human disease. Pathogenic species belonging to the genus *Treponema* are responsible for yaws, endemic syphilis, pinta, periodontal disease, as well as venereal syphilis discussed here. *T. pallidum* is an obligate human parasite, with no animal or environmental reservoirs. It is a helical corkscrew-shaped Gram-negative bacterium, 6–20 µm in length and 0.10–0.18 µm in diameter, placing it below the resolution of light microscopy. The unstained organism is best visualized by dark field or phase-contrast microscopy. *T. pallidum* generally stains poorly with many dyes but can be visualized using silver impregnation techniques. Like other Gram-negative bacteria, *T. pallidum* has an outer membrane, an inner membrane, and a thin cell wall consisting of peptidoglycan. The outer membrane is unusual, however, in that it lacks lipopolysaccharide, thus rendering it more susceptible to damage resulting from physical disruption or detergent use during handling. The outer membrane also contains relatively few proteins, which may account for the limited antibody response seen with this pathogen. *T. pallidum* is also unusual in that it has flagella, located in between the inner and outer membranes, which are

responsible for its characteristic motility, consisting of rapid rotation along its longitudinal axis, as well as bending and flexing. This motility is believed to play an important role in the organism's ability to invade and disseminate.

T. pallidum is a fastidious organism and has not been successfully cultured *in vitro*, and thus diagnosis depends on direct visualization and serologic testing. For study purposes, viable organisms can, however, be maintained for several weeks in tissue cell culture. The organism appears to be microaerophilic and is very sensitive to environmental conditions, being easily inactivated by mild temperature fluctuations, desiccation, and chemical agents including most disinfectants. These characteristics have hampered the study of the organism. Recently, the complete genome of *T. pallidum* was successfully sequenced. The genome consists of 1 138 006 bp containing 1041 predicted coding sequences. The information gained from sequencing has helped to elucidate systems for DNA replication, transcription, translation, and repair, as well as possible virulence factors and metabolic processes. Potential virulence factors include a family of 12 membrane proteins and several putative hemolysins. Catabolic and biosynthetic capabilities appear to be limited. Glucose is the main carbon and energy source for *T. pallidum*, although pyruvate appears to be an alternative.

The pathogenesis of *T. pallidum* is not well understood. Following penetration of mucosal surfaces, *T. pallidum* appears to adhere to host cells and then begins multiplication. The organism has been shown to adhere to a variety of cell types, perhaps through an interaction with fibronectin and host cell receptors. After multiplication, the organisms disseminate via the bloodstream and invade distant organs, aided by their unusual motility. Lesion resolution is thought to be the result of cell-mediated immunity, involving phagocytosis by macrophages activated by lymphokines and opsonic antibodies, released from antigen-specific sensitized T and B cells. Despite the destruction of millions of organisms, some persist and eventually cause the later stages seen in syphilis. There are several possible mechanisms by which the organism escapes the host immune response, probably the most important of which is the paucity of outer membrane proteins that would ordinarily provide ample targets for the immune response. In addition, *T. pallidum* may also have some surface components that inhibit complement-mediated killing. Secondary syphilis results from the dissemination and further multiplication of persistent organisms. Some manifestations may also result from immune complex deposition, especially with regard to the skin and kidney involvement seen at this stage. After a period of latency, persisting organisms may cause damage to the central nervous system, the cardiovascular system, and other organs in patients with tertiary syphilis. Here, much of the damage seen is likely due to the associated immunological response of the host.

Perspectives and Overview of Single Particle Cryo-Electron Microscopy

Macromolecules, as they interact in the cell, drive the processes that constitute life in bacteria, plants and animals. They function as architectural elements, tracks, transporters, catalysts, receptors, channels, and storage compartments. They provide mechanical support, generate movement, catalyze thousands of essential reactions, and control growth, to name some of their roles in the cell. The function of a macromolecule as it interacts with others is constituted by its unique three-dimensional structure and its propensity to undergo conformational changes in a highly specific way. Many macromolecules or supramolecular assemblies are considered “molecular machines” as they contain moving domains and perform work cycles in a highly processive way. Biophysical methods to determine their three-dimensional structure include X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy, and cryo-electron microscopy (cryo-EM). To date, most of the structures in the public database by far (~140,000) have been determined by X-ray crystallography. This method requires the macromolecules to be packed into highly-ordered 3D-crystals, which rarely exist in nature. Obtaining such highly organized crystals, however, is a major challenge for many macromolecules. Single-particle cryo-EM is rapidly becoming a preferred method for structure determination because of the ability of the technique to image molecules without the need for crystallization. These include large, multi-component, and flexible structures, molecule-ligand combinations in multiple stoichiometries, as well as many membrane proteins.

The single-particle approach to visualization is based on the assumption that a given molecule exists in numerous “copies” randomly oriented in the sample, and its images can be interpreted mathematically as a collection of projections of a rigid body (or several distinct bodies) in different orientations. In single-particle cryo-EM, specifically, the EM grid is prepared by pipetting the sample containing the molecules onto the grid, blotting off excess liquid, and plunging the grid rapidly into a cryogen at liquid-nitrogen temperature. Under those conditions, water is transformed into vitreous ice, which closely resembles the liquid state, without expansion of volume characteristic for crystalline ice. The EM grid so prepared is then imaged at liquid-nitrogen temperature in the transmission electron microscope, yielding a data set of projection images. Using a variety of program packages, one or several three-dimensional images (often referred to as “reconstructions” or “density maps”) are reconstructed from these projections, providing the basis for modeling the structure of the molecule. Depending on the resolution of the reconstruction, modeling entails the use of existing structures in the database (“flexible fitting”) or sequence-directed fitting of structural elements (amino acids for proteins, nucleotides for RNA). Structural details at resolutions in the range 2–4 Å have now been demonstrated for an increasing number of biological macromolecules. Notably, even individual water molecules and ions at the expected coordinating distances can be observed within the density maps.

Principle of Cryo-EM of Biological Molecules

For electrons to travel in the column of the electron microscope, a high vacuum must be maintained. Unlike most samples in the Materials Science field, biological molecules usually are hydrated. The difficulties of imaging them were initially overcome by using

a technique termed *negative staining*, where heavy-metal salt is added to the solution of molecules, and the sample is air-dried on the grid. A layer of heavy-metal salt forms around each molecule, preventing its collapse and, at the same time, providing strong contrast through stain exclusion. However, the molecule is dehydrated and deformed in the process, and interior details of the structure are not visualized.

An efficient way to overcome the problem of vacuum incompatibility and preservation of native structure is the frozen-hydrated specimen preparation technique, developed by Jacques Dubochet and colleagues. In this method, the biological molecules are embedded in a thin layer of ice that is kept at a temperature where evaporation is negligible. The term “cryo-electron microscopy,” abbreviated cryo-EM, has been coined to describe this preparation and imaging method. It is synonymous with the less often used term “electron cryomicroscopy,” also abbreviated “cryo-EM.”

Cryo-EM Specimen Preparation

The basic specimen preparation technique involves an apparatus that rapidly plunges the grid into liquid ethane held at a temperature in the range of -170 to -180°C (Fig. 1). Under these conditions, vitreous ice is formed, and the formation of crystallized ice, deleterious for the molecule, is prevented. First, a droplet of the liquid sample ($2\text{--}3\ \mu\text{L}$) containing the molecules is applied to the EM grid that is mounted on tweezers fastened to a vertically-mounted rod. Excess liquid ($\sim 99\%$) is blotted off such that only a thin liquid film remains (ideally in the range of $800\text{--}1000\ \text{\AA}$). Next, the EM grid is plunged into liquid ethane through the release of the gravity-operated rod. After the plunge, the grid is first transferred into a storage box containing liquid nitrogen, from which it is later transferred to a cryo-specimen holder, to a cartridge, or an autogrid, depending on the type of electron microscope. In all these transfers, ideally, the grid is always kept at the temperature of liquid nitrogen. The grid is finally inserted into the EM.

Fig. 1 Schematic diagram of a freeze-plunge apparatus. The EM grid, on which the specimen is suspended within a thin water layer, is held at the tip of tweezers, which are in turn mounted on a steel rod that is held vertically, in a position to fall under gravity. The thickness of the water layer is controlled by blotting off excess sample prior to plunging. As the rod is released, the grid is rapidly plunged into a bath of liquid ethane or propane at liquid-nitrogen temperature. Owing to the rapid decrease in temperature, the water turns into vitreous ice, which has properties akin to those of liquid water. Most importantly, no crystals are formed, and a disruption of the molecule is avoided.

The correct thickness of the ice in which the molecules are suspended is critical for obtaining interpretable images. With increasing thickness the proportion of inelastic to elastic scattering increases. Since only the former carries useful information, the thickness is restricted to less than 2000 Å, beyond which the sample essentially turns electron-opaque. On the other hand, a thickness close to, or smaller than, the size of the biological molecule will lead to the formation of damaged, partially “freeze-dried” samples, and images bearing little resemblance to the molecule. The main parameters determining the thickness of the vitreous ice layer are blotting time, temperature, humidity, and the length of time the blotted sample is exposed to these conditions before the fast plunge.

The purification of biomolecules, especially membrane proteins, often poses problems such as limited solubility of the protein in water, limited purification yield per batch, and the difficulty to closely match the physiological environment. Due to these problems the grid preparation often results in unproductive sessions on the electron microscope. Technology is now under development that allows smaller amounts of sample to be used to prepare the cryo-EM grid, and to use the large surface area of the grid for trying out multiple buffer conditions. Along these lines, two promising techniques have been developed, both involving robotic hardware: (1) Spotiton and (2) cryoWriter. Both of these techniques are automated, require no blotting, and only need pico- to nano-liter amounts of volume to prepare each grid.

Time-Resolved Cryo-EM Specimen Preparation

In time-resolved EM studies, a biological reaction is stopped at one or multiple time points by fast-freezing. Biologically relevant fast reactions, on the time scale of tens of milliseconds, can be studied by cryo-EM, because the rapid-freezing step itself takes merely a fraction of a millisecond. However, imaging snapshots of such fast reactions require a means of mixing, reacting and depositing the product on the grid in a fast, controlled way. In the mixing-spraying method developed by Lu *et al.* mixing and reacting are achieved in a monolithic silicon chip, a microfluidic device with two inlets for solutions to be mixed and one spray outlet which sprays the reaction product onto the grid with the help of inert driving gas (Fig. 2). While the time for mixing itself is fixed and in the range of 0.5 ms for all chips, the mean reaction time varies for different chips and is defined by the length of a

Fig. 2 Experimental setup of the mixing-spraying method and the design of the mixing-spraying chip. (a) Experimental setup. Two solutions (1 and 2) are injected into the mixing-spraying chip, mixed and reacted for a short, defined time. The mixture solution meets compressed nitrogen gas (Gas) and is sprayed into a plume of droplets, which hit the EM grid as it is plunged into the cryogen. The resulting grid is covered with thin blobs of vitreous ice in which the molecules are trapped. (b) Design of the mixer. The two solutions which enter with a total flow rate of 6 $\mu\text{L/s}$ are mixed completely within 0.5 ms in the four tandem butterfly-shaped mixer channels. (c) Design of the reaction channels with different lengths. The length of the reaction channel is varied to achieve different reaction times (from 4 to 1000 ms) on different chips.

meandering or spiraling reaction chamber, which in the present design can be varied in the whole range from 4 to 1000 ms. The combined time of flight for the spray and the plunging of the grid adds another 5–40 ms, depending on the geometry of the apparatus.

Unlike the conventional pipetting-blotting-plunging technique, the spraying-plunging method allows the sample to be deposited on the grid in a controlled way. Controlling parameters are driving gas pressure and distance between the spray nozzle and the grid. With a series of microfluidic chips at different reaction times, all short-lived intermediates on the reaction pathway, along with the structures of the initial components and the end products, can be visualized. In the first biological application of this technique, short-lived intermediates during the processes of translation initiation and termination have been visualized. Future developments in the time-resolved method include reduction of sample consumption, shortening of the minimum effective reaction time, and optimization of droplet size and distribution on the EM grid.

Imaging in the Electron Microscope

Electron microscopes use electrons to image the sample. As negatively charged particles, they are repelled by electrons surrounding the nucleus of atoms. This interaction causes the incoming electrons to scatter. There are three possible outcomes. If the electrons pass through in between atoms and do not interact with them at all, they are called unscattered electrons. The second outcome is a scattering event without dissipation of energy (“elastic scattering”), such that a coherent relationship is maintained between scattered and un-scattered beam, the origin of productive, high-resolution image formation. The third outcome, in contrast, is a scattering event accompanied by energy loss (“inelastic scattering”), leading to an incoherent relationship between scattered and un-scattered beams and making no productive contribution to the image.

Elastically scattered electrons undergo a phase shift by $\pi/2$. Further phase shifts are introduced by the wave aberrations of the lens – mainly spherical aberration – and by operator-controlled defocussing. The size of these additional phase shifts is dependent on the scattering angle. In bright-field imaging, the normal imaging mode, phase contrast is created by the interference between scattered and unscattered electrons. Phase contrast is alternately positive and negative in successive zones of the Fourier transform of the image, with bands of zero contrast in between, as described by the (phase) contrast transfer function (CTF). In addition, a small contribution to the total contrast comes from amplitude contrast.

The CTF is a function of the spatial frequency, or the radius in the Fourier transform of the bright field image, and it depends on two parameters: the spherical aberration constant of the objective lens, and the defocus setting. Without correction for the effects of the CTF, neither the images nor the 3D reconstruction derived from them will be faithful representations of the object (Fig. 3). One of the problems of bright-field imaging, reflected by the shape of the CTF, is the fact that low spatial frequencies of the object’s Fourier transform, representing the overall contrast of the particle, are strongly suppressed. This affects the ease with which small particles can be located in the micrographs by particle-picking software.

For the purpose of CTF correction, a series of images are taken in the EM with different defocus settings, so as to cover the entire Fourier domain up to the band limit (the spatial frequency limit up to which information is present) without any gaps. The information from this “defocus series” is then merged in Fourier space using a weighting function termed *Wiener filter*.

In instruments equipped with a *phase plate*, an extra $\pi/2$ phase shift is introduced in the path of the primary beam, resulting in constructive interference between the primary beam and elastically scattered electrons starting at low spatial frequencies. As a result, particles stand out strongly in the image from the background, and even small molecules are easily picked by automated software. The Volta phase plate (Thermo-Fischer, Waltham, MA, United States), the only commercially available device, comprises a thin (~ 10 nm) amorphous carbon film constantly heated to $\sim 250^\circ\text{C}$. The phase shift is created “on-the-fly” by the interaction of the central diffraction beam with the film. However, exposure to the electron beam changes the properties of the carbon film, changing the phase shift over time and requiring periodic adjustments.

The main limitation to directly visualizing high-resolution details of individual biological molecules, as compared to conventional electron microscopy in the Materials Science field, is the damage inflicted by the electrons at the large dosages required to define the image statistically. Thus radiation damage limits the information in electron micrographs of biological specimens. Electron diffraction measurements at the beginning of the 1970s by Robert M. Glaeser and coworkers showed the electron diffraction patterns of 2D crystals formed by L-valine to disappear after exposure to as little as $6\text{ e}^-/\text{\AA}^2$. Crystals of the less sensitive adenosine ceased to diffract at an exposure of about $60\text{ e}^-/\text{\AA}^2$, still much lower than the “normal” conditions for taking an exposure.

There are three categories of damage caused by inelastic scattering, the destructive interaction of electrons with frozen-hydrated specimens: (1) primary interactions: excitation, ionization or displacement of an atom; (2) secondary effects: further chemical reactions caused by the secondary electrons and free radicals in the specimen, for example, bond breakage or cross-linking; and (3) tertiary effects: damage from temperature rise, electrostatic charging and morphological change. Cooling to low temperature increases the biological material’s resistance to radiation damage. The reason for the reduction of damage is that free radicals produced by ionization during electron irradiation are trapped under these conditions, preventing, or at least reducing, the visible damage to the structure. Even with this provision, it is necessary to reduce the electron dose to a range below $\sim 30\text{ electrons}/\text{\AA}^2$, resulting in so-called *shot noise* superimposed on the signal. This noise is effectively eliminated as a result of averaging, by using large numbers of projections of the molecule in computing the reconstruction.

Energy filters are devices whose purpose is to block electrons that have suffered energy loss (“inelastic scattering”), and therefore do not contribute in a coherent way to the image of the molecule, but rather to the background. In thick ($> 0.25 \mu\text{m}$) specimens, contributions by inelastic scattering to the image are strong, and may make the image uninterpretable. There are two types of energy filter that have been developed for TEM, “in-column” and “post-column”. The in-column filter has the spectrometer built into the path of the electrons in the column. The post-column energy filter is a “magnetic prism” mounted right below the place where the final image is formed in normal EM. The main application of energy filters is in electron tomography of cell sections, which are at the crucial thickness range where inelastic scattering is starting to overwhelm the image.

Recording Media

For decades, the only recording medium for EM was the photographic film. As digital processing of micrographs started, the direct recording of images in the EM using a fluorescent screen with fiber-optic coupling to a charge-coupled device (CCD) became an attractive alternative, despite the shortcomings of this recording medium. These shortcomings were limited resolution or small field size, and relatively poor detective quantum efficiency (DQE), a measure of the efficiency of the detector to record quanta of radiation. Recently, in 2012, the most significant advance in recording has been made by the introduction of direct electron detection cameras. These utilize a complementary metal oxide semiconductor (CMOS) chip with a direct detection device (DDD) sensor, and have a performance far superior to film and CCD cameras.

In direct electron detection cameras, the capture of multiple frames is necessary to avoid saturation of electron counting. A high internal frame rate of 50 per second (Falcon 3EC, Thermofisher) to 1500 per second (K3, Gatan) is used so that in each frame the individual primary electron events can be identified and counted. The capture of multiple frames also offers two advantages. First,

Fig. 3 Effect of the CTF. Ribosome reconstruction with (a) and without correction for the effect of the CTF (b).

by selective use of a subset of frames for reconstruction, one can minimize radiation damage to the specimen. Secondly, stage drift and beam-induced motion of particles in vitreous ice can be readily compensated. Electron counting and beam-induced motion correction enable near-atomic-resolution single-particle cryo-EM.

Image Processing

Raw images of the sample recorded do not allow us to get immediate insights, for three reasons: (1) they are extremely noisy as a consequence of the low dose required to curb radiation damage to the molecule, (2) the information about the molecule is scrambled on account of the CTF, and (3) they depict only two-dimensional projections of the structure. To obtain noise-free unscrambled three-dimensional information for the sample, we need to do an extensive amount of image processing. There are numerous steps of image processing that bring us from the raw data to the finished product, the three-dimensional image (Fig. 4).

The first step is to align frames recorded in movie mode to remove, at least partially, beam-induced motion. Algorithms for correcting beam-induced motion have been developed by many groups, for example unblur, Motioncor2 and optic flow. The most commonly used algorithm for drift correction of the movies recorded from the Gatan K2 camera is Motioncor2. Here, the frames are divided into patches, and drift within each patch is separately determined. The reason to do so is for correction of anisotropic local motion. The molecule has multiple modes of movement, shifting in the image projection plane (X-Y plane), shifting up and down along the Z-axis, and rotation. Then all frames are summed with or without radiation-damage weighting. As mentioned in the previous section, recording in movie mode allows the effective radiation damage to be minimized in the three-dimensional image. High-resolution features (i.e., the conformation of amino acid side chains) decay faster than low-resolution features (i.e., backbone structure of a protein). This means that for a given dose, low-resolution information is still present in the later frames, but high-resolution information is lost.

The next step is to estimate the CTF. Accurate estimation of the CTF and properly correcting for it is extremely important for the quality of the high-resolution reconstruction. The principle for estimation of the contrast transfer function is to maximize the cross-correlation of a simulated power spectrum based on the estimated CTF with the power spectrum of the experimental image. Many different programs perform this task. The most popular ones are CTFFIND3, CTFFIND4, GCTF and Warp.

Fig. 4 Cryo-EM single particle data processing work flow. Microscope beam-induced drifts are corrected by dividing the frames into patches and calculating each drift. All frames are summed with or without radiation damage-weighting. The micrographs are visually inspected to remove those with crystalline ice and large drift, etc. Next, the CTF of each micrograph is estimated. Particles are manually picked to create references. Auto-picking utilizes the references to automatically pick particles for all micrographs. The picked particles are extracted for further classification. The extracted particles are sorted into classes to remove classes with noisy or contaminated particles and any possible “false picks”. Using a 3D reference map, the “good” classes are assigned to different 3D classes to marginalize orientation and class assignments of particle images. The accuracy of orientation is further optimized in 3D refinement.

The third step is to obtain the coordinates for projection images of molecules (particles) in each image. This step is usually referred to as *particle picking*. Over the years, many stand-alone software or modules of larger packages have been developed to pick particles semi-automatically or automatically. Various techniques including cross-correlation, variance mapping, intensity comparisons, texture-based methods, segmentation/edge detection have been explored and used in this step. Neural networks and deep learning are in increasing use for automatic particle picking.

No particle picking program is perfect. Each one has its own merits and drawbacks. Common issues are that too many false particles are picked or that too many true positives are missed. Part of the problem is that the molecules whose projections are picked as “particle” may be partially damaged due to radiation damage or damage resulting from interaction with the air-water interface. As a consequence, the delineation between “false” and “true” particles is blurred in practice.

In the following steps, individual particle images are extracted from the micrographs based on the coordinates determined in the particle picking step. Ideally, each particle image contains the particle in its center, and some background around the particle. Sometimes the particles are too crowded in the micrograph, and in that case an image based on the selection by particle picking may contain more than one particle. To remove the false picks, two-dimensional (2D) classification is applied to the extracted images. In the 2D classification step, all the extracted particles are aligned and sorted iteratively into different classes representing different projections of the 3D object. In this classification, false picks are readily recognized as outliers as they lack common features and fail to form high-resolution class averages with high numbers of class members.

After the particles in the “good” classes have been pooled together, a strategy for 3D reconstruction has to be determined based on the amount of prior knowledge about the molecule structure. Either a 3D reference map is already available, which might be a low-resolution map of the same or a similar sample, or a reference map has to be first created by some kind of bootstrap reconstruction technique.

In the latter case, there are several ways to obtain a 3D reference. One of these is the random-conical tilt method. In this method, one identifies a subset of particles with closely matching orientation on the grid. Two images are taken of the same field of particles, one at zero tilt angle, and one at a high tilt angle. With this collection geometry, the orientation of each particle of the subset can be determined, and a provisional reconstruction can be built that can serve as a reference for subsequent refinement. Another method uses a set of 2D class averages to build up a 3D map employing the technique of common lines. A third method starts with a small set of class-averages and builds a set of 3D maps by an iterative procedure.

A complication arises from the fact that samples are often heterogeneous. Molecules may possess compositional or conformational heterogeneity, or both. In this case, images need to first be sorted into homogeneous classes in a step termed 3D classification. In this step, using a maximum-likelihood approach, probability distributions for both orientation and class assignments for each particle image are determined, and multiple 3D reconstructions are refined at the same time. In the first iteration, all particles are first assigned randomly to each class and then refined against the low-resolution 3D reference. For a few iterations, global search is performed with an angular sampling rate of 15° or 7.5° . In these coarse beginning steps, large compositional or conformational differences are immediately distinguished. Because the actual number classes for a given specimen is unknown, one may need to determine it by trial and error, by repeating the 3D classification with different numbers of classes. If there are still small residual compositional or conformational differences within each class, indicated by a blurred region in the 3D reconstruction, finer classification – focusing only on the blurred region with smaller angular degrees 3.75 or 1.8 degrees – will be needed.

Orientation angles of all particles are further improved in accuracy in the refinement step, run for each homogenous class separately. All particle images, assumed to represent exactly the same object from different angles, are iteratively aligned to the reference. After each iteration, the reference is updated and the angular sampling rate is decreased (from 7.5 down to 0.45 degrees or smaller), resulting in improved resolution. For resolution estimation, the particle set is split into half sets that are refined independently. Thus, at each iteration of the refinement, the resolution can be estimated from a comparison of the running half set reconstructions in Fourier space. To this end, the Fourier Shell Correlation (FSC) is commonly used. For truly independent half set reconstructions, $\text{FSC} = 0.143$ is an accepted resolution criterion.

Several comprehensive software packages exist with specialization in electron microscopy, among these CISTEM, EMAN, FREALIGN, IMAGIC, JSPR, RELION, SPIDER, THUNDER, and XMIPP. Each of these is a more or less tightly integrated collection of modules, designed to perform the entire processing job. However, there is an increasing trend toward the use of modules from multiple platforms, mixing and matching these as they have different strengths and weaknesses in different areas of the methodology. APPION and SCIPION are examples of platforms designed for this purpose. Both provide transparent interconversions between the different file formats and angle conventions used in the various packages.

Structure Interpretation

Some medium- or low-resolution 3D maps represent complexes formed by molecules of known atomic structure. For interpretation of such 3D maps, we dock the known structures into the maps. Integration of the knowledge gained from other techniques such as cross-linking or mass spectroscopy is becoming increasingly important in the interpretation of medium- or low-resolution 3D maps.

Fig. 5 High-resolution features in a cryo-EM single particle reconstruction of AAV2L336C at 1.86 Å resolution. (a) Stereo view of a slice through the map and model containing both amino-acid residues and water molecules. (b) Stereo view of a slice through a beta sheet. (c) Map densities for each of the 20 types of amino-acid residues. The amino acid residues are shown as stick representation and colored according to atom type: C = yellow, O = red, N = blue, S = green inside either a translucent solid density ((a), (b)) or black mesh density map (c). H = white atoms are displayed for (c). Figure reproduced with permission from Tan, Y.Z., Aiye, S., Mietzsch, M., *et al.*, 2018. Sub-2 Å Ewald curvature corrected structure of an AAV2 capsid variant. *Nature Communications* 9, 3628.

However, if the 3D map approaches a resolution of 3.5 Å or better, *de novo* model building becomes possible. Segmentation is usually the first challenge in interpreting a 3D density map *de novo*. Because a 3D map often contains multiple subunits, segmentation is necessary to divide the 3D map into single polypeptide or nucleic acid chains (Fig. 5). At high resolution, the identity of each amino acid in a protein is readily distinguishable based on the shape of the side chain. Likewise, in RNA or DNA, the identity of the bases can be inferred from their characteristic signatures. Many model building tools are now available that originated from model building techniques in X-ray crystallography, such as Phenix and Coot. Some tools are for automatic model building, such as phenix autobuild, Buccaneer and Rosetta structure prediction.

WSH	Wheat straw hydrolysate
WWI and WWII	World War I and World War II

Defining Statement

Production of butanol (acetone–butanol–ethanol (ABE)) from agricultural products employing novel technologies. The article details production of AB from various novel substrates, in various types of reactors, and using a number of product recovery technologies. In this article, a brief description of various cultures that are available for butanol production has been given.

Introduction

Butanol (acetone–butanol–ethanol, ABE or AB or solvents) production is one of the oldest fermentation processes employed for commercial production of a chemical to benefit mankind. Production of butanol was discovered by Pasteur in 1861. Its production by fermentation comes second to ethanol in importance and history as there were commercial plants that were operational during World War I (WWI) and WWII. It should be noted that after the WWII (between the 1950s and 1960s), butanol fermentation could not compete with petrochemically derived butanol due to the development of petrochemical industries. The last biobased butanol plant ceased operations in the early 1980s in South Africa due to a shortage of molasses, the feedstock for this fermentation, brought on by drought, and the high cost of recovery. Butanol can be produced by fermentation employing a number of microorganisms

[☆]*Change History*: September 2016. N. Qureshi revised article title; updated author affiliation and text of the article; added new sections “Novel Substrates” and “Novel Product Recovery Technologies”; and additional abbreviations were added to Abbreviation section.

This article is an update of N. Qureshi, Solvent Production, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 512–528.

such as *Clostridium acetobutylicum*, *Clostridium beijerinckii*, *Clostridium saccharoperbutylacetonicum*, *Clostridium saccharobutylicum*, and genetically altered *Escherichia coli*. The typical ratio of ABE in the final product is usually 3:6:1 with maximum concentration of total solvents (ABE) being 20 g L^{-1} when using traditional strains and traditional batch fermentation process. Recovery of butanol from such a dilute product is cost intensive when recovered by distillation (traditional technology).

Currently, butanol is produced using either the oxo process from propylene (with H_2 and CO over a rhodium catalyst) or the aldol process starting from acetaldehyde. Acetone (a co-product of the butanol fermentation), is produced either by the cumene hydroxide process, or the catalytic dehydration of isopropanol. These chemical synthetic routes have proven to be economically superior compared to the fermentation based processes. Since 1990, production of butanol in the United States has been constant ($1.20 \times 10^9 \text{ kg year}^{-1}$), while worldwide production has fluctuated slightly. The worldwide annual production of acetone and butanol has been of the order of 2.1×10^9 and $2.5 \times 10^9 \text{ kg}$, respectively. Butanol has numerous applications as an automotive fuel and in the chemical industry. When used as an automotive fuel butanol contributes to clean air by reducing emissions such as unburned hydrocarbons in the tail pipe exhaust. Butanol possesses superior fuel properties compared to ethanol. As compared to ethanol's research and motor octane values of 111 and 92, these values for butanol are 113 and 94, respectively. The heat of vaporization for butanol is $141.3 \text{ k cal kg}^{-1}$ as compared to $204.1 \text{ k cal kg}^{-1}$ for ethanol. In addition, the high boiling point (118°C) and lower vapor pressure for butanol should enhance cold starting. There are various other properties that make butanol a superior fuel. It has 30% higher energy content per liter as compared to ethanol, is less miscible with water, and more miscible with gasoline and diesel fuel.

Recently, there has been renewed interest in fermentation derived butanol both as a potential fuel and as a chemical feedstock. Continuously rising and/or fluctuating prices and increased dependence on foreign fuel have been major driving factors for the increased interest in butanol as a motor fuel replacement. Increased oil prices in 1973 resulted in a revival of research activities on a number of fermentations, including ethanol and butanol, with a long range view toward becoming less dependent on foreign oil. As a consequence, research was focused on developing technologies to produce fuels and chemicals from readily available and abundant renewable agricultural resources. As a result some degree of success was achieved in numerous countries when bioconversion programs involving alcohol fuel production were examined. Brazil had introduced its ethanol production program in 1977 followed by the United States. Soon after this low oil prices were restored. However, constant conflicts in the oil supply regions and rising oil prices have reminded the world that alternate energy sources be sought for future energy independence. With this view the United States has initiated various energy initiatives including replacing 30% of transportation fuel by ethanol by 2030. In 2006 approximately $14.62 \times 10^9 \text{ kg}$ (4.7 billion gallons) of ethanol was produced from corn (in the United States) which is approximately 3.5% of total fuel consumption ($413.7 \times 10^9 \text{ kg}$ or 133 billion gallons) in the United States. In 2015, annual production of ethanol from corn increased to $46.0 \times 10^9 \text{ kg}$ (14.8 billion gallons). It is anticipated that up to $65.3 \times 10^9 \text{ kg}$ (21 billion gallons) (15%) of ethanol can be produced annually from corn without affecting food and feed supply. Further increases in ethanol production would likely require the use of cellulosic biomass such as corn fiber, corn stover, wheat straw, or energy crops like switchgrass and miscanthus.

Intensive research efforts were focused on this fermentation during the early 1980s with the overall objective to make butanol fermentation economically competitive. As a result of research intensification, a number of problems associated with this fermentation were identified including cost ineffective recovery of butanol by traditional recovery technology (distillation), low butanol concentration in batch reactor ($<20 \text{ g L}^{-1}$), and low productivity ($<0.50 \text{ g L}^{-1} \text{ h}^{-1}$) due to butanol inhibition. An account of some of these problems and their possible solutions has been documented in literature. Because of this research, highly productive continuous reactor systems and butanol recovery technologies were developed not only to recover butanol economically but to relieve butanol inhibition in the reactor systems. This gave birth to "integrated" technologies where production of butanol was combined with product recovery. Combination of production and recovery technologies resulted in the use of higher amount of substrates, improvement in productivities, and achieving a more concentrated product stream to be presented for further recovery and purification. These research and development activities were aimed at use of substrates such as whey permeate (from dairy industry) and glucose (from wet milling corn industry).

In the author's opinion, research activities slowed during 1990s due to the reduction or stabilization of gasoline prices. The years 2002–07 once again witnessed sharp increases in gasoline prices which prompted a considerable increase in research activities in this fermentation, in particular bioconversion of economically available lignocellulosic biomass to butanol. Substrates such as corn fiber, wheat straw, barley straw, corn stover and sweet sorghum bagasse (SSB) have been used to produce butanol. Additionally, waste streams such as food waste have also been used. Although productive reactors were not used for these applications, some recovery technologies have been successfully integrated for production of butanol from some of these agricultural residues. In this article, it is the author's aim to give latest information to the reader on production of these biofuels, in particular butanol, and various process technologies such as recovery of butanol using adsorption, pervaporation, liquid–liquid extraction, and gas stripping. Process integration is a fascinating technology which allows use of concentrated sugar solutions, thus reducing process streams and economizing production of butanol from agricultural residues, and wastes or by-product streams. As a result of recent technological developments in butanol fermentation, and recovery, Dupont (United States) and British Petroleum (United Kingdom), have been working on the commercial development of butanol or isobutanol production processes from biomass. Other ongoing efforts relating to the commercial production of butanol from biobased substrates include those of Green Biologics (1-butanol or n-butanol), and Cobalt Technologies (1-butanol). It is noteworthy that China has emerged as a large scale producer of butanol from biobased materials such as corn (Cathay Industrial Biotech). Currently, Dow, Exxon Mobile, BASF, and Eastman Chemical Companies produce butanol on a large scale by chemical synthesis.

Problems of AB Fermentation

Traditionally AB is produced in batch reactors. A typical batch fermentation system is initiated with 60 g L⁻¹ substrate, usually glucose, cornstarch, molasses, or whey permeate. During the course of fermentation (36–72 h) this sugar is converted to <20 g L⁻¹ ABE, resulting in a productivity of 0.5–0.6 g L⁻¹ h⁻¹ and a yield of 0.30. Such a low product concentration is due to product (butanol) toxicity. Inhibition begins at a butanol concentration of as low as 10 g L⁻¹ and stops fermentation at 20 g L⁻¹ total ABE. As a result batch AB fermentation suffers from low productivity (0.5–0.6 g L⁻¹ h⁻¹) as compared to ethanol (usually 2–3 g L⁻¹ h⁻¹), and results in the use of dilute sugar solution (60 g L⁻¹ as compared to approximately 150 g L⁻¹ for ethanol), and low yield. In ethanol fermentation, a product concentration as high as 130 g L⁻¹ can easily (can be higher than that) be achieved. Additionally, recovery of AB from dilute product stream requires a large amount of energy for product separation. The author is not aware if water can be recycled from this process in commercial scale plants as all such plants are located in China. However, if water can be recycled, it would be a significant economic gain. The recycling of water was considered in some of our economic evaluations. For these reasons (low AB concentration in the broth, low productivity, low yield, lack of water recycle, and high recovery costs), economic viability of commercial butanol fermentation has been a challenge.

Traditional Substrates

Sugarcane Molasses

Cane molasses was successfully used in the commercial production of butanol in South Africa (National Chemical Products (NCP) Germiston, South Africa) until the early 1980s. Unfortunately, fermentation of butanol was terminated due to molasses shortage caused by severe drought. Molasses contains approximately 50% sucrose which can be hydrolyzed to glucose and fructose by butanol producing cultures. This substrate is easy to handle as it requires only dilution prior to fermentation. There are a number of molasses types which can be used including beet, blackstrap, and invert (high-test) molasses.

Whey Permeate

Whey permeate is a byproduct of cheese making industry which contains 44–50 g L⁻¹ lactose, that makes it a suitable substrate for AB fermentation. The substrate (lactose) content in whey permeate varies from process to process. For other fermentations such as ethanol it is an unsuitable substrate (unless the medium is supplemented with additional sugar) because of its relatively low sugar content. However, whey permeate has numerous applications in the fermentation industry which have been documented in the literature. Various types of whey permeates have been used for the production of butanol using *C. acetobutylicum* P262 (the industrial strain) suggesting that it is a good substrate for this fermentation. However, in a batch reactor productivity of the order of 0.1 g L⁻¹ h⁻¹ is obtained. It should be noted that this substrate is a rich source of minerals and hence further supplementation with minerals to the fermentation medium is not required. Extensive studies have been reported on the use of this substrate for ABE fermentation process which included development of immobilized cell reactors and product recovery systems.

Soy Molasses

Spray dried soy molasses (SDSM) is a by-product of the soy processing industry and contains 746 g kg⁻¹ sugar of which 434 g kg⁻¹ is fermentable. The fermentable sugars that are present in soy molasses include glucose, sucrose, fructose, and galactose while nonfermentable sugars include pinitol, raffinose, verbascose, melibiose and stachyose. Soy molasses has been used to produce ABE using *C. beijerinckii* BA101. The culture was able to utilize fermentable sugars and produced 10.7 g L⁻¹ ABE from 80 g L⁻¹ SDSM. However ABE up to 22.8 g L⁻¹ was produced when 80 g L⁻¹ SDSM was supplemented with 25.3 g L⁻¹ glucose suggesting that 80 g L⁻¹ SDSM was deficient in fermentable sugars and that was the reason for poor (10.7 g L⁻¹) ABE production using SDSM alone as a carbon source. Further increase in SDSM concentration was not beneficial for growth or ABE production due to presence of excessive amount of salt in this substrate. It has been determined that *C. beijerinckii* BA101 was not able to ferment raffinose, pinitol, melibiose, verbascose, and stachyose due to its inability to hydrolyze the α -1-6 glycosidic bond present in these sugars. In order to be able to use these nonfermentable sugars a strain should be developed with a capability of hydrolyzing α -1-6 glycosidic bonds. Development of such a strain will result in the more complete utilization of sugars present in SDSM. Alternately, soy molasses should be supplemented with isoamylase or hydrolyzed using dilute/mild acid treatment.

Potatoes

Since clostridia possess strong amylolytic activity, substrates containing starch have been considered for this fermentation. These substrates include corn, rye, cassava, and potatoes. Potatoes and potato wastes are economically viable substrates. Although it has been suggested that this substrate has viscosity problems, both hydrolyzed and unhydrolysed potatoes have been successfully used for butanol production using *C. acetobutylicum* or *C. beijerinckii* strains. Using unhydrolyzed potatoes, an initial potato starch concentration of 45 to 48 g L⁻¹ was used in the fermentation thereby producing up to 12 g L⁻¹ ABE. Potato starch hydrolysate

obtained with α -amylase and amylo-glucosidase prior to the fermentation resulted in the production of 11.4 and 10.4 g L⁻¹ total ABE, respectively. This suggested that hydrolysis prior to fermentation was not limiting the fermentation and the culture was able to hydrolyze potato starch to glucose efficiently during the fermentation.

Substrates Based on Grains

As stated above solventogenic clostridia can hydrolyze starch and produce ABE without a need for separate hydrolysis process. Hence corn, millet, wheat, rice and tapioca have been used as substrates for this fermentation. Butanol can also be produced both by using corn co-product from: (1) corn dry grind and (2) wet milling processes. During the dry grind process corn fiber and germ are not typically removed before fermentation. At the end of fermentation (after starch utilization during fermentation) corn fiber and other insoluble solids are removed by centrifugation, dried and sold as cattle feed. The dried solids are known as “Distillers Dry Grains and Solubles” or DDGS. On the contrary, during the wet milling process, corn fiber and germ are removed prior to fermentation. In this process cornstarch can be converted to any of the three products (liquefied cornstarch, glucose sirup, or glucose) each of which is fermentable by *C. beijerinckii* to produce butanol. It should be noted that often corn refineries add sodium metabisulfite during the wet milling operation as a corn kernel softening agent and preservative to the liquefied corn starch (LCS). The presence of sodium metabisulfite may interfere with the direct fermentation of the liquefied corn starch. However, glucose sirup or glucose does not contain any such fermentation inhibitors.

Cassava and Jerusalem artichokes have also been investigated as potential substrates for butanol fermentation. It has been reported that cassava alone was not a suitable substrate, but could be used successfully when supplemented with 20% corn meal or other sources of organic nitrogen. Jerusalem artichoke is a potential agricultural crop that contains carbohydrates that can be used for AB production. The carbohydrates present in the tuber occur mainly in the form of short oligomeric fructans which have an inulinic structure and must be hydrolyzed by acid or inulinase prior to AB fermentation. Also supplementation of the hydrolysate with corn or soy meal was reported to be necessary. The use of Jerusalem artichoke has also been investigated as a part of French research program on the production of fuel extenders from biomass. Hydrolysates were prepared using enzyme treatment with inulinase and, apart from ammonia, no nutritional supplements were added to the fermentation medium. After a period of 36 h, 23–24 g L⁻¹ of solvents was obtained.

Liquefied Corn Starch

Liquefied corn starch (LCS) is a potential industrial substrate that can be used for AB production. It is a product of corn wet-milling process and is composed of 35–40% dry solids as reducing sugars and dextrans. In order to avoid microbial contamination, sodium metabisulfite, a microbial inhibitor, is added to this substrate. In one of the studies on the use of this substrate for butanol production, concentrations of glucose, reducing sugars, and sodium metabisulfite were measured to be 5.58±0.26, 337.5±2.12 and 0.71±0.10 g L⁻¹, respectively. It has been reported that this concentration of sodium metabisulfate is inhibitory for growth of *C. beijerinckii* BA101. Hence to reduce the inhibitory effect of this chemical on cell growth, it was diluted seven times. This resulted in the production of comparable (compared to glucose) amount of ABE in a batch reactor. This substrate was also saccharified (saccharified liquefied corn starch, SLCS) prior to feeding to a fed-batch reactor integrated with product recovery.

Novel Substrates

The high cost of substrates including molasses, whey permeate, corn, and starchy roots has been identified as a major factor affecting the economic viability of butanol production by fermentation. In order to produce butanol cost competitively, use of more economic substrates must be evaluated. These substrates include agricultural residues and energy crops such as corn stover, corn fiber, switchgrass, miscanthus, and wheat, barley and rice straws. It should be noted that butanol producing cultures are able to utilize a wide variety of carbohydrates (including hexoses, pentoses, and cellobiose) such as sucrose, glucose, fructose, mannose, lactose, dextrin, starch, xylose, and arabinose. The use of these carbohydrates by butanol producing cultures illustrates the potential to ferment sugars derived from hydrolysates of agricultural residues to butanol.

Corn Fiber

Recently, it was demonstrated that corn fiber (CF) could be used to produce butanol. Corn fiber was hydrolyzed using dilute (0.5%, v/v) sulfuric acid at 121°C for 1 h followed by cooling to 45°C and adjusting pH to 4.5. The mixture was then treated with enzymes (cellulase and cellobiase) for 72 h under agitation (150 rpm). Following hydrolysis, the pH of the mixture was raised to 6.5 followed by fermentation to produce butanol. The culture was unable to produce more than 1.7 g L⁻¹ ABE, due to inhibition caused by salts (neutralization product) and other inhibitory products formed during hydrolysis. However, the hydrolyzate was successfully fermented after removal of these inhibitors. The inhibitors were removed partly by overliming the hydrolyzate and partly by treating it with a nonionic polymeric adsorbent resin (Amberlite XAD-4).

Wheat Straw

Attempts have been made to produce butanol from wheat straw (WS) hydrolyzate. WS was hydrolyzed using dilute (1%, v/v) sulfuric acid at 121°C for 1 h followed by cooling to 45°C and adjusting pH to 5.0 using 10 M KOH solution. The mixture was then hydrolyzed with enzymes (cellulase, xylanase, and β -glucosidase) for 72 h followed by filter sterilization. The hydrolyzate (pH raised to 6.8) was then fermented to butanol using *C. beijerinckii* P260. In these studies no inhibition due to salts or inhibitory products was observed. Rather fermentation was more rapid than control batch fermentation where glucose was used as a substrate. These studies demonstrated that hydrolyzates of some of the agricultural residues can be fermented to butanol with little inhibition. In addition to the novel substrates mentioned in this section (Section V) of the article, substrate such as distillers' dry grain solubles (DDGS) has been explored at the University of Illinois (Urbana, IL, United States) for butanol production using a number of clostridial strains including *C. acetobutylicum*, *C. beijerinckii*, *C. saccharobutylicum* and *Clostridium butylicum*.

The composition of WS on dry basis is presented in Table 1.

Barley Straw

Although barley straw appears to be similar to wheat straw, its hydrolysate's fermentation characteristics were found to be different than wheat straw hydrolyzate. Prior to detoxification, barley straw hydrolyzate (BSH) did not produce more than 7.09 g L⁻¹ ABE resulting in a poor ABE productivity of 0.10 g L⁻¹ h⁻¹, which were improved to 26.64 g L⁻¹, and 0.39 g L⁻¹ h⁻¹, respectively, upon detoxification using overliming technique. However, wheat straw hydrolyzate was successfully fermented to butanol without any detoxification and the culture produced 25.00 g L⁻¹ total ABE. These results suggest that BSH can be fermented, however, it has to be done at the expense of additional, overliming, detoxification process step.

Corn Stover

Unlike wheat straw and barley straw hydrolysates, corn stover hydrolysates (CSH) were found to be difficult to ferment to butanol. In a CSH solution, the culture showed no cell growth and no fermentation prior to the removal of inhibitors by overliming. Upon inhibitor removal, the culture produced 26.27 g L⁻¹ ABE with a productivity of 0.31 g L⁻¹ h⁻¹. In this fermentation an ABE yield of 0.44 was obtained. Compared to the other substrates, CS hydrolyzate was relatively difficult to ferment.

Food Waste

Food waste (FW) is a substantial pollution problem in the United States and many other countries in the world, in particular when it is used to incinerate or landfill. In the United States alone more than 33 million (33×10⁶) tons of food waste was generated in 2012, which included discarded food by food processing industries, restaurants, and consumers. It is assumed that approximately 33 million tons is generated each year. There are several major advantages with the use of FW for butanol production: (1) it contains significant amount of sugars or carbohydrates that can be used for this fermentation; (2) it does not require pretreatment as opposed to cellulosic feedstocks; (3) it contains proteins, fatty acids, and minerals that can be used as nutrients for cell growth and fermentation by the culture; (4) its availability is expected to be at much lower cost than cellulosic biomass; and, (5) it addresses environmental pollution problem. Keeping these advantages in view, we have successfully produced butanol from this substrate.

Municipal Waste/Domestic Organic Waste

Both Municipal Waste (MW) and Domestic Organic Waste (DOW) can be used as feedstocks for butanol production with similar kind of advantages listed in the above Section V(E). In a report on production of butanol from DOW, it was mentioned that this

Table 1 Composition of wheat straw on dry solid basis

Component	Dry solids (% w/w)
Cellulose	48.6±0.3
Hemicellulose	27.7±0.1
Lignin	8.2±0.9
Acid detergent fiber	58.9±0.0
Neutral detergent fiber	86.6±0.1
Crude protein	3.5±0.1

feedstock contained 25.1 g glucose, 8.4 g xylose, and 5.8 g other monosaccharides per 100 g dry matter. DOW was used to produce ABE and IBE (isopropanol, butanol, ethanol) with some degree of success. It is emphasized that every source of carbohydrates should be used to produce butanol.

There are other substrates that have been used for this fermentation including industrial wastes (starch based packing peanuts), orchard wastes such as apple drops and apple pomace, and sugarcane factory wastewater. Due to space limitation, details of these feedstocks are not presented in this article.

Hydrolysis Inhibitors of Agricultural Residues

As mentioned in the corn fiber section, dilute acid (0.5%, v/v) hydrolysis of this substrate resulted in poor fermentation of the hydrolysate. In order to ferment CF hydrolyzate (CFH) to ABE, the CFH was treated with molecular sieve to remove fermentation inhibitors. Upon treatment, the CFH was fermented successfully, suggesting that inhibitors prevented fermentation of CFH. In another study, attempts were made to quantify effect of inhibitors such as salts, furfural, hydroxymethyl furfural (HMF), syringaldehyde, and acetic, ferulic, *p*-coumaric, and glucuronic acid on cell growth and product formation. Furfural, HMF, and acetic acid (as acetate) did not inhibit fermentation at the concentrations that were attempted. On the contrary when 0.3 g L⁻¹ each of ferulic, and *p*-coumaric acids were added to the fermentation medium cell growth and ABE production decreased significantly. Fermentation with added furfural, and HMF was found stimulating to the fermentation. A comparison with CFH, CSH and WSH (wheat straw hydrolysate) demonstrated that generation of inhibitors is substrate specific. It was noticed that fermentation of WSH was vigorous and no inhibition was observed.

Microbial Cultures and Culture Development

A number of strains that produce significant amounts of solvents from different carbohydrates have been reported in the literature. These cultures include *C. acetobutylicum* P262 (renamed as *C. saccharobutylicum*), *C. acetobutylicum* ATCC 824, *C. acetobutylicum* NRRL B643, *C. acetobutylicum* B18, *C. beijerinckii* P260, *C. beijerinckii* BA101, *C. beijerinckii* LMD 27.6, *C. butylicum*, *Clostridium aurantibutyricum*, and *Clostridium tetanomorphum*. *C. saccharobutylicum* P262 and *C. beijerinckii* P260 were industrial strains that were used for commercial solvent production in South Africa until early 1980s. These butanol producing strains are distinguished based on the ratio and type of solvents production. *C. butylicum* produces isopropanol rather than acetone while *C. aurantibutyricum* produces all three solvents including acetone, isopropanol, and butanol. *C. tetanomorphum* produces equal amounts of butanol and ethanol and does not produce acetone or isopropanol.

It should be noted that significant research efforts have focused on developing or genetically improving butanol producing cultures. A group in Germany isolated strains that produced up to 29.1 g L⁻¹ total solvents. Attempts were also made to improve *C. acetobutylicum* ATCC 824 to produce more solvents than the parental strain. The new strain was able to produce up to 30 g L⁻¹ total solvents. *C. beijerinckii* BA101 was developed from *C. beijerinckii* 8052 and the newly developed strain has been reported to produce up to 25.6–33 g L⁻¹ total ABE. *C. beijerinckii* P260 has been reported to produce 23.1–28.2 g L⁻¹ total ABE.

Biochemistry and Metabolic Pathways

A brief description of biochemical pathways involved in AB production from corn has been described in literature. During solvent production, the culture passes through three phases known as cell growth, acidogenic (acetic and butyric acid production) followed by solventogenic (assimilation of acids and conversion into acetone and butanol). In the early stages of acidogenic phase cell growth also occurs. During acidogenic phase hydrogen and a large amount of ATP are produced. During the acidogenic phase the pH of the culture medium drops from an initial pH of 6.8 to approximately 5.0. As solventogenesis begins, pH starts to rise from 5.0 to 6.8–7.0. In the solventogenic phase hydrogen and ATP production decreases. Carbon dioxide gas is produced during both acidogenic and solventogenic phases (two moles are produced from each mole of glucose metabolized to pyruvate; CO₂ production in the solventogenic phase is higher as an additional mole is produced for every mole of acetone produced). It has been suggested that the switch to solvent production is an adaptive response of the cell to the medium pH resulting from acid production. It has been reported that clostridia that are able to utilize cellulose produce little or no ABE.

In solventogenic clostridia, the uptake of carbohydrates occurs through a phosphoenolpyruvate (PEP) dependent phosphotransferase system (PTS). This mechanism involves uptake and simultaneous phosphorylation of carbohydrates. In the case of glucose, it is converted to glucose-6-phosphate which is subsequently metabolized to pyruvate via the Embden–Meyerhof–Parnas (EMP) pathway. Fructose is converted to fructose-1-phosphate and enters the EMP pathway upon conversion to fructose 1,6-diphosphate. As the culture is able to utilize pentose sugars such as xylose and arabinose, D-xylose is converted to D-xylulose by the xylose isomerase enzyme and the metabolism proceeds by a phosphorylation reaction. The reaction is catalyzed by xylulose kinase which results in the formation of D-xylulose-5-phosphate. The pentose phosphate pathway utilizes enzymes transaldolase and transketolase to convert D-xylulose-5-phosphate to glyceraldehyde-3-phosphate and fructose-6-phosphate. The glyceraldehyde-3-phosphate and fructose-6-phosphate enter the EMP pathway resulting to the formation of pyruvate. The solventogenic clostridia

have advantage over other cultures such as yeasts used for ethanolic fermentation as the former (clostridia) can utilize both hexoses and pentoses derived from lignocellulosic biomass. Table 2 shows conversion of various sugars to pyruvate which is then converted to acids and/or ABE by EMP pathway.

Fig. 1 shows a simplified biochemical pathway for AB production. During acidogenic phase 3.25 mol of ATP are formed per mol of glucose. The enzymes phosphate acetyltransferase and acetate kinase convert acetyl-CoA to acetate and similarly phosphate butyltransferase and butyrate kinase convert butyryl-CoA to butyrate. The acetic and butyric acids produced during fermentation may be freely permeable to the cell membrane and these acids equilibrate the internal and external (in fermentation broth) pH. Both pH reduction and accumulation of acetate and butyrate have been associated with triggering solventogenesis.

During solventogenic phase ATP production is reduced to 2 mol per mol of glucose. In this phase butyric and acetic acids are reassimilated by the action of acetoacetyl-CoA:acetate/butyrate:CoA transferase. This enzyme catalyzes the reaction that transfers CoA from acetoacetyl-CoA to either acetate or butyrate. Acetate is converted to acetyl-CoA, followed by conversion to acetone, butanol, or ethanol. Butyrate is converted to butyryl-CoA followed by conversion into butanol. This happens as there is no metabolic pathway to regenerate acetyl-CoA from butyryl-CoA. As a result of removal of CoA from acetoacetyl-CoA, acetoacetate is produced, which is transformed directly into acetone and CO₂ by acetoacetate decarboxylase.

In acidogenic and solventogenic pathways a series of reactions occur that produce butyryl-CoA from acetyl-CoA. The enzyme thiolase condenses two molecules of acetyl-CoA into one molecule of acetoacetyl-CoA. Acetoacetyl-CoA is reduced to 3-hydroxybutyryl-CoA by hydroxybutyryl-CoA dehydrogenase. This results in the formation of crotonyl-CoA (by dehydration) and is catalyzed by crotonase. The carbon–carbon double bond in crotonyl-CoA is reduced with NADH to produce butyryl-CoA. The last reaction is catalyzed by butyryl-CoA dehydrogenase.

The accumulation of butyric and acetic acids and butanol in the fermentation broth is toxic to the culture which causes cell death. As a result of shift to solventogenesis, fermentation is extended. However butanol produced reaches toxic levels. The presence of butanol in the membrane increases membrane fluidity and destabilizes the membrane and membrane-associated processes.

Use of Concentrated Sugar Solutions

As stated in Section III of this article, in a typical batch fermentation system sugar concentration in excess to 60 g L⁻¹ is rarely used due to inhibition caused by butanol. However attempts have been made to use concentrated sugar solutions. In a batch system *C. acetobutylicum* P262 (renamed as *C. saccharobutylicum* P262) was grown in a medium containing 200 to 227 g L⁻¹ lactose (in whey permeate medium). In a similar approach *C. beijerinckii* BA101 was grown in a medium containing 159–165 g L⁻¹ glucose. In another report on the use of concentrated sugar solution, *C. beijerinckii* P260 was able to grow and produce AB in solution containing 200 g L⁻¹ glucose. Hence, it has been found that sugar tolerance is culture specific. Although, these cultures can grow in concentrated sugar solutions, they cannot utilize all the sugar present in the system. Other substrates where concentrated sugar solutions have been used include LCS, SLCS, WSH, BSH, and CSH (supplemented with glucose). The reader is advised to read Section X(B) and learn how complete sugar utilization has been possible in this fermentation. Table 3 shows sugar tolerance of various butanol producing cultures.

Table 2 Carbohydrates that can be used by solventogenic clostridia for ABE production

A. Glucose
Glucose→glucose-6-phosphate→pyruvate
B. Fructose
Fructose→fructose-1-phosphate→fructose-1,6-biphosphate→pyruvate
C. D-Xylose
D-Xylose→D-xylulose→D-xylulose-5-phosphate→glyceraldehyde-3-phosphate+fructose-6-phosphate→pyruvate
D. Agricultural biomass
Agricultural biomass→hexoses+pentoses (upon hydrolysis). Then steps A and C follow
E. Cellobiose
Cellobiose→glucose. Then step A follows
F. Sucrose
Sucrose→glucose+fructose (upon hydrolysis). Then steps A and B follow
G. Starch
Starch→glucose. Then step A follows
H. Inulin
Inulin→fructose. Then step B follows
I. Dextrin
Dextrin→glucose. Then step A follows

Note: Hydrolysis of agricultural biomass (D) to hexose and pentose sugars requires pretreatment with acid/alkali and hydrolysis by enzymes. Inulin (H) requires hydrolysis by inulinase. Solventogenic *Clostridia* cannot hydrolyze these substrates efficiently.

Fig. 1 Simplified metabolism of polysaccharides by solventogenic *clostridia*. Table 3 Production of AB from concentrated sugar solutions using various butanol producing cultures in batch reactors

Culture	Initial sugar (g L ⁻¹)		Residual sugar (g L ⁻¹)
<i>Clostridium acetobutylicum</i> P262	lactose	227	0
<i>Clostridium beijerinckii</i> P260	glucose	200	0
<i>C. beijerinckii</i> BA101	glucose	159–165	0
<i>C. acetobutylicum</i> ATCC824	glucose	60	(Fed-batch system)

Bioreactors for Fermentation

Bioreactors play an important role in fermentation industry that impact production cost. However, their use depends on a particular application. A variety of reactors have been used for the production of chemicals such as AB. These reactors include batch, continuous stirred tank (suspended cell), compartmentalized (immobilized cell), fed-batch, fluidized bed (immobilized cell) and membrane cell recycle reactors. The details of these reactors are presented in the individual sections below.

Batch Reactors

Traditionally, batch reactors are used in fermentation industry to produce chemicals such as butanol and ethanol. In a batch process, the reactor is charged with a substrate solution (60–80 g L⁻¹) followed by sterilization, cooling, and inoculation with actively growing culture. The fermentation is run for a specified duration depending upon the culture and the substrate used. For butanol

fermentation process, the reactor is run from 36 to 72 h and during this time period approximately 20–33 g L⁻¹ total ABE (ratio 3:6:1) is produced depending upon the culture used. The ABE concentration in the fermentation broth is limited due to butanol inhibition to the cell. At the end of fermentation, cell mass is removed by centrifugation or settling. The cell mass so recovered is sold as cattle feed. During fermentation, temperature is controlled at 35–37°C and pH at approximately 5.0. After removal of cell mass, the fermentation beer is sent for solvent removal which is usually by distillation. Fig. 2 shows a typical batch fermentation profile using cornstarch as a substrate.

During medium cooling, nitrogen or carbon dioxide is swept across the surface to keep the medium anaerobic. After inoculation, the medium is sparged with these gases to mix the inoculum. Depending on the size of the final fermentor, the seed may have to be transferred several times before it is ready for the production fermentor. Various substrates (outlined in Sections IV and V) can be used to produce butanol. It should be noted that some substrates may require processing prior to fermentation known as “upstream processing” such as dilution, hydrolysis, concentration, centrifugation, or filtration, etc.

During the 1940s and 1950s, production of butanol (from corn) on an industrial scale (Terre Haute, IN and Peoria, IL; both in the United States) was carried out using large fermentors ranging in capacity from 200,000 to 800,000 L. The industrial process used 8–10% corn mash, which was cooked for 90 min at 130–133°C. Corn contains approximately 70% (dry weight basis) starch. The use of molasses offers a number of advantages over using corn including the presence of essential vitamins and micronutrients. In industrial processes beet, invert, and blackstrap molasses were diluted to give a fermentation sugar concentration of 50 to 75 g L⁻¹, most commonly 60 g L⁻¹. The molasses solution was sterilized at 107 to 120°C for 15 to 60 min followed by adding organic and inorganic nitrogen, phosphorus, and buffering chemicals. The yield of solvent using *C. acetobutylicum* was usually low at 0.29–0.33. Distillation has been the method of choice to recover butanol, however, during the last three decades a number of alternative techniques have been investigated for the economical recovery of butanol which will be discussed in the Recovery Section XI.

Batch Process With Concentrated Sugar Solutions

Due to the butanol toxicity, the initial substrate concentration in a batch reactor is limited to <80 g L⁻¹ (usually 60 g L⁻¹). A substrate concentration in excess of this results in a high residual substrate, thus resulting in inefficient sugar utilization and increased biological oxygen demand (BOD) load for wastewater treatment. However, recent developments in simultaneous recovery of AB have made it possible to use concentrated sugar solutions for this fermentation. During the fermentation, the toxic products such as butanol are removed simultaneously, thus relieving inhibition which results in the utilization of more substrate. The details of the various recovery techniques have been given in the Recovery Section XI. Employing butanol removal techniques, sugar solutions containing 161.7 g L⁻¹ glucose (*C. beijerinckii* BA101) and 227 g L⁻¹ lactose (*C. saccharobutylicum* P262) have been successfully fermented. Use of concentrated glucose and lactose solutions has resulted in the production of 76 and 137 g L⁻¹ ABE, respectively. In such fermentations, less acids are produced, thus improving the ABE yield. In another process, 200 g L⁻¹ lactose was successfully fermented in a batch reactor of *C. saccharobutylicum* P262 when integrated with product recovery by gas stripping. This system resulted in the production of 70 g L⁻¹ ABE with a productivity of 0.32 g L⁻¹ h⁻¹ as compared to 0.07 g L⁻¹ h⁻¹ in the control batch reactor. Studies reported in this section demonstrated that a fermentation medium containing over three times the sugar concentration as compared to a batch reactor can be successfully fermented when integrated with product removal techniques. Sugars were used to exhaustion in these fermentations (Table 3).

Boca Raton, FL: CRC Press, Taylor & Francis Group, pp. 99–122 (Fig. 6.2). HAc, acetic acid; HBu, Butyric acid.

Fed-Batch Reactors

Fed-batch reactors are usually employed when the substrate is toxic to the culture. In such a case, the reactor is initiated in a batch mode with a low substrate concentration (usually 60–100 g L⁻¹) and low fermentation medium volume, usually less than half the volume of the fermentor. Upon inoculation the culture initiates utilizing substrate. As the substrate is used by the culture, a fresh feed solution containing concentrated sugar is added to the reactor at a rate that is equal to utilization of substrate. Both the liquid volume and product concentration increase with time. As the culture volume reaches near 70% of the reactor volume, the fermentation is stopped and product is harvested. This kind of system is applied to the production of chemicals that are not so toxic to the culture. An example of this process is bioconversion of glucose to 2,3-butanediol. Using fed-batch technique, 2,3-butanediol in excess of 100 g L⁻¹ can accumulate in the fermentation broth.

Since butanol is toxic to *C. acetobutylicum* or *C. beijerinckii* cells, the fed-batch fermentation technique cannot be applied in this case unless one of the novel product recovery techniques is applied for simultaneous recovery of butanol. In a number of studies this technique has been applied successfully to the ABE fermentation. In a fed-batch fermentation up to 500 g glucose in 1 L culture volume (500 g L⁻¹) was used as compared to 60 g L⁻¹ in a control batch process.

In a study, a substrate of whey permeate (lactose 350 g L⁻¹) was used to produce butanol in a fed-batch reactor of *C. acetobutylicum* P262. In this process, four different techniques of butanol separation were compared including liquid–liquid extraction, perstraction, gas stripping, and pervaporation. In the four processes, 23.8, 57.8, 69.1 and 42.0 g L⁻¹ ABE were produced, respectively. ABE yield of 0.35, 0.37, 0.38, and 0.34 were obtained, respectively. Overall, application of these four techniques suggested that fed-batch fermentation technique can be applied to the ABE fermentation provided ABE is removed from the culture broth simultaneously.

In another study, ABE was produced in a fed-batch fermentation of *C. acetobutylicum* (ATCC 824) and the solvents were recovered using a silicone–silicalite synthesized pervaporation membrane. The reactor was fed with a concentrated (700 g L⁻¹) glucose solution. In this system, 155 g L⁻¹ ABE was produced with an average yield of 0.31–0.35 and productivities ranging from 0.13 to 0.26 g L⁻¹ h⁻¹. Using the fed-batch technique, fermentation of more sugars (2–3 times) was possible when novel product removal techniques were applied to the fermentation process. For further details on product separation the reader is advised to read “Novel product recovery technologies” (Section XI).

Continuous Bioreactors

Batch reactors often result in low productivity due to down time or the time required for harvesting, cleaning, re-filling, sterilization, cooling and then growing culture again for the next batch. In a batch reactor each time the culture is inoculated, cell growth is slow. The time required that the culture takes to grow is known as lag time. A continuous reactor does not encounter these problems as a bioreactor inoculated once may run for a long time. As a result of elimination of down time, reactor productivity is improved. There are three types of continuous bioreactors that can be used for butanol production. These reactors include suspended cell, immobilized cell, and cell recycle continuous bioreactors.

Suspended cell continuous bioreactors

The continuous culture technique may be used to improve reactor productivity and study the physiology of the culture in steady state. For continuous fermentation of butanol a number of studies have been carried out. Laboratory studies have demonstrated that due to production of fluctuating levels of solvents and complexity of butanol fermentation, the use of a single stage continuous reactor does not seem to be practical at the industrial scale. In continuous culture, a serious problem exists in that solvent production may not be stable for long time periods and ultimately declines over time, with a concomitant increase in acid production. In a single stage continuous system high reactor productivity may be obtained, however this occurs at the expense of low product concentration in the effluent when compared to that achieved in a batch process. In a single stage continuous reactor 15.9 g L⁻¹ total solvents was produced at a dilution rate of 0.1 h⁻¹ resulting in a productivity of 1.5 g L⁻¹ h⁻¹. In order to improve the productivity, the dilution rate was increased to 0.22 h⁻¹, thus improving productivity to 2.55 g L⁻¹ h⁻¹. However the product concentration decreased to 12 g L⁻¹. In a more recent study, a continuous fermentation was run in order to study the effect of fermentation gases and dilution rate on solvent production. In this system a productivity of 0.58 g L⁻¹ h⁻¹ was obtained at a dilution rate of 0.07 h⁻¹, thus producing 8.3 g L⁻¹ total solvents. In order to improve reactor productivity a single stage spin filter perfusion bioreactor has also been used. In the perfusion bioreactor a maximum productivity of 1.14 g L⁻¹ h⁻¹ was obtained, however, solvent concentration fluctuated over time.

Two or more multistage continuous fermentation systems have been investigated to reduce fluctuations and increase solvent concentration in the product stream. This is done by allowing growth, acid production and solvent production to occur in separate bioreactors. In a two stage continuous system a solvent concentration of 18.2 g L⁻¹ was reported using *C. acetobutylicum* DSM 1731 which is comparable to the solvent concentration in a batch reactor. This type of multistage reactor system (7–11 fermentors in series) was successfully tested at the pilot plant and full scale plant level in Russia (then Soviet Union).

Immobilized cell bioreactors

Batch, fed-batch, and suspended cell continuous reactors result in low reactor productivity due to low cell concentrations caused by butanol toxicity. In a batch reactor a cell concentration <4 g L⁻¹ is achieved. In a butanol batch process, reactor productivity is

limited to less than $0.50 \text{ g L}^{-1} \text{ h}^{-1}$ due to a number of reasons including low cell concentration, down time, and product inhibition. In order to increase reactor productivity, cell concentration inside the reactor should be increased. It should also be noted that suspended cell reactors cannot be operated at high flow rate due to cell washout. Hence methods to retain high cell concentration inside the reactor and still operate the reactor at high flow rates, have been developed. These methods are known as “cell immobilization” and “cell recycle”. By using cell immobilization method, cell concentration in excess $50\text{--}70 \text{ g L}^{-1}$ can be achieved in the reactor. Such reactors can be operated at high flow rates with no cell washout. Cell recycle method will be discussed later.

Cell immobilization can be grouped in three different categories, namely adsorption, entrapment, and covalent bond formation. Adsorption is a simple technique where cells adsorb onto surfaces of various materials such as wood shavings, bonechar, glass wool, clay brick, etc. Adsorption is a natural process, and this technique does not require any chemicals for attaching cells to the surfaces. Often adsorption process is carried out inside the reactor. The reactor is packed with adsorbent followed by inoculation with the culture and feeding the reactor with a nutrient solution. Packed bed reactors show quicker growth than fluidized bed reactors.

Entrapment is another technique where cells are enclosed in gel layers such as calcium-alginate, poly-acryl-amide, or carrageenan. In order to immobilize cells by entrapment, cells are grown in batch reactors followed by harvesting them by centrifugation, mixing with a gel suspension/solution followed by passing through a needle to form gel beads. The gel beads containing cells may require further treatment such as hardening or polymerization. The beads thus formed are either packed in a reactor or suspended in a continuous stirred tank reactor (CSTR) for chemical production. Immobilization by covalent bond formation require chemicals such as glutaraldehyde to bond cells to the support of choice. It should be noted that some of the chemicals that are used to bond the cells may be toxic to the culture.

Increased reactor productivity results in the reduction of process vessel size and capital cost thus improving process economics. In an attempt to improve the reactor productivity use of immobilization techniques such as entrapment and adsorption has been investigated for this fermentation. While entrapment resulted in low productivities, adsorption was able to offer productivities as high as $4.5\text{--}6.5 \text{ g L}^{-1} \text{ h}^{-1}$. Fig. 3 shows an electron micrograph of adsorbed cells of *C. acetobutylicum* P262 on bonechar. The cells were heavily adsorbed onto the support and formed as many as 36 single cell layers. In an attempt to explore use of clay bricks as an adsorption support, cells of *C. beijerinckii* BA101 were adsorbed onto this support with a reactor productivity of $15.8 \text{ g L}^{-1} \text{ h}^{-1}$. In another approach a group from the Ohio State University (Columbus, OH, United States) immobilized cells of *C. acetobutylicum* on a fibrous support which was used in a continuous reactor to produce ABE. This system resulted in a maximum reactor productivity of $4.6 \text{ g L}^{-1} \text{ h}^{-1}$.

Cell recycle membrane reactors

As described above, microbial cells are immobilized using one of the three techniques called adsorption, entrapment, and covalent bond formation. In all three cases the culture may experience diffusion limitations including substrate, product, and nutrients. In substrate diffusion limitation, the inner most cells may not receive carbon source required for its energy needs thus resulting in death of these cells. This will reduce amount of active cells that take part in the reaction. Starvation or diffusion limitation may inactivate a significant amount of cells thus resulting in reducing reactor productivity. At the same time product diffusion limitation may not allow diffusion of toxic products from the cell surroundings thus affecting cell viability. Both of these problems can result in significantly reduced productivity.

Similarly as cell immobilization increases cell concentration inside the bioreactor, cell recycle membranes are other means of increasing cell population inside the reactor. Unlike immobilized cell particles, the cells remain suspended in the liquid medium. Membrane is used as a means of preventing the cells from going with the out flow. Using membrane cell recycle reactors, cell concentrations as high as 100 g L^{-1} can be achieved inside the bioreactor. In these reactors there is no nutrient limitation to the cells as opposed to the immobilized cell reactors. Using this approach, reactor productivities up to $6.5 \text{ g L}^{-1} \text{ h}^{-1}$ (as compared to $<0.5 \text{ g L}^{-1} \text{ h}^{-1}$ in batch fermentation) have been achieved in the butanol fermentation. In a similar approach a single stage spin filter perfusion bioreactor was used which resulted in a maximum productivity of $1.14 \text{ g L}^{-1} \text{ h}^{-1}$, however, the ABE concentration fluctuated over time. Fig. 4 shows schematic diagrams of various reactor types that have been used for butanol production.

Novel Product Recovery Technologies

Adsorption-Based Technologies

Adsorption is a simple technique to separate solvents by adsorbing onto a number of adsorbents known as silicalite, resins (XAD-2, XAD-4, XAD-7, XAD-8, XAD-16), bone charcoal, activated charcoal, bonopore, and polyvinylpyridine. In order to separate butanol, the adsorbent and fermentation beer are brought in contact where the solvents are selectively adsorbed followed by recovering the product by heat treatment (of the adsorbent). The adsorption process occurs adequately at room temperature. The adsorption capacity of different adsorbents varies from 48 to 206 mg g^{-1} adsorbent. It has been reported that use of silicalite is better than other adsorbents as butanol from dilute solutions (5 g L^{-1}) can be concentrated to approximately 790 g L^{-1} . A number of investigators have used actual fermentation broth to separate butanol or ABE. In one of the investigations a comparison was made between total ABE produced and total sugar utilized in the control and integrated fermentation. In a control batch fermentation 13.5 g ABE was produced from 43.8 g sugar, while in the integrated batch fermentation 23.2 g of ABE was produced from 73.3 g sugar. These studies were extended to a repeated fed-batch fermentation system in which 1198.5 g sugar was used and 387.3 g ABE was produced. A schematic diagram of adsorption is shown in Fig. 5(A).

Recovery Based on Extraction and Perstraction

Extraction or Liquid–liquid extraction has been considered to be an important technique for the recovery of ABE from fermentation broths. A water-insoluble organic extractant is mixed with the fermentation broth where butanol being more soluble in the organic phase than in the aqueous (fermentation broth) phase is extracted. Therefore, butanol selectively concentrates in the organic phase. Because the extractant and fermentation broth are immiscible, the extractant can easily be separated from the fermentation broth by phase separation after butanol extraction. It should be noted that liquid–liquid extraction is able to remove fermentation products without removing substrates, water, or nutrients.

In order to enhance substrate utilization and improve productivity, liquid–liquid extraction must be integrated with the butanol fermentation, in a manner that simultaneous fermentation and butanol removal from the fermentation broth is achieved. The choice of extractant is important because an extractant with low partition coefficient will not be efficient in the recovery of butanol and a toxic extractant will inhibit cell growth and fermentation or kill the bacterial cells. Unfortunately, most extractants with high partition coefficient are toxic to the clostridia. However, the extractant of choice among researchers has been oleyl alcohol because it is seen as a non-toxic good extractant.

During extraction, a number of problems such as emulsion formation, accumulation of bacterial cell mass at the organic–aqueous interphase, toxicity to the culture, and loss of extractant during phase separation are encountered. In order to solve these problems, a selective membrane is placed in between aqueous phase and organic phase. The membrane contactor provides surface area where the two immiscible phases can exchange the butanol. Since there is no direct contact between the two phases, extractant toxicity, phase dispersion, emulsion and rag layer formation are drastically reduced or eliminated. In such a system, butanol should diffuse preferentially across the membrane, while other components such as medium compositions, microbial cells, and fermentation intermediates (acetic and butyric acids) should be retained in the aqueous phase. The total mass transport of butanol from the fermentation broth to the organic side depends on the rate of diffusion of butanol across the membrane. The membrane does, however, present a physical barrier that can limit the rate of solvent extraction.

Recovery Using N₂ or Fermentation Gases (CO₂ and H₂)

Gas stripping is a simple technique that can be applied for recovering solvents (ABE) from model solution or the fermentation broth. Oxygen free nitrogen or fermentation gases (CO₂ and H₂: produced during solvent fermentation) are bubbled through the fermentation broth followed by cooling the gas (or gases) in a condenser. As the gas is bubbled through the broth in the fermentor, it captures ABE which is condensed in the condenser followed by collection in a receiver. Once the solvents are condensed, the gas is recycled back to the fermentor to capture more ABE. This process continues until fermentation stops due to lack of sugar (as a result of utilization of all the sugar). In some cases a separate stripper can be used to strip off solvents followed by recycling the stripper effluent that is low in ABE. Fig. 5(B) shows a typical schematic diagram of solvent removal by gas stripping.

Gas stripping has been successfully applied to remove solvents from batch, fed-batch, fluidized bed, and continuous reactors. In addition to removal of solvents, a concentrated sugar solution was fed to the reactors to reduce the volume of process streams and economize the butanol fermentation process. The reader is referred to Section X(B) (Batch process with concentrated sugar solutions) and Section X(C) (Fed-batch fermentation) of this article where concentrated sugar solutions were successfully fermented in combination with product recovery using this technique. In these processes, the reactor productivities, and product yield were also improved. Additional advantages of gas stripping included achieving a high ABE concentration in the condensed stream for further recovery and the requirement for no membrane or chemicals for the recovery process.

Membrane Based Recovery Such as Pervaporation

Pervaporation is a simple technique that allows selective removal of volatiles from model solutions/fermentation broths using a membrane. The volatile organic component (AB in this case) diffuses through the membrane as a vapor followed by recovery by condensation. During this process, a phase change occurs from liquid to vapor. Since it is a selective removal process, the desired component requires a heat of vaporization at the feed temperature. In pervaporation, the effectiveness of separation of a volatile is measured by two parameters called selectivity (a measure of selective removal of volatile) and flux (the rate at which an organic volatile passes through the membrane per m² membrane area). A schematic diagram of the pervaporation process is shown in Fig. 5 (C). Application of pervaporation to batch butanol fermentation has been described by numerous investigators. Pervaporation has also been applied for the removal of butanol from the fermentation broth in fed-batch reactors. In the fed-batch reactors concentrated sugar solutions have been used to reduce the volume of process streams. It is interesting to note that acids did not diffuse through some of the membranes.

In an attempt to improve membrane selectivity, the two techniques known as liquid–liquid extraction and pervaporation were combined to recover butanol. The extraction solvent used for this process was oleyl alcohol which formed a thin liquid layer (known as a thin membrane) on a microporous 25 µm thick polypropylene flat sheet. The oleyl alcohol got impregnated into the sheet pores. In this combination of liquid–solid membrane, oleyl alcohol dissolved butanol relatively quickly followed by diffusion through the polypropylene membrane. The advantage of combining the liquid (oleyl alcohol) and solid membrane was that a high butanol selectivity (180) was achieved in comparison to a low selectivity (10–15) when using polypropylene film alone. It should be noted that a membrane of selectivity 180 would concentrate 5 g L⁻¹ feed butanol to 475 g L⁻¹ butanol in a single pass, while a membrane of selectivity 15 would concentrate the same feed to 70 g L⁻¹ butanol. A product containing 475 g L⁻¹ butanol is 6.79 times more concentrated than 70 g L⁻¹. It was estimated that if this solid–liquid pervaporation membrane with a selectivity of 180

were used for butanol separation, the energy requirement would be only 10% of that required in a conventional distillation. Unfortunately, the membrane was not stable as the oleyl alcohol that formed a thin film and was impregnated into the polypropylene film pores diffused out of the membrane during the recovery process.

In order to develop a stable and high selective membrane, two techniques known as adsorption and pervaporation were employed. It is known that adsorption of butanol onto silicalite and molecular sieves is a quick and selective process. Hence a membrane was synthesized in which silicalite was included into a silicone membrane. By combining this, butanol selectivity was improved from 40 (silicone membrane) to 209. The membrane so developed was called silicalite–silicone membrane and the performance of this membrane was found to be stable with a working life of 3 years. This membrane was used to separate butanol from both butanol model solutions and fermentation broths. A comparison of various pervaporation membranes suggested that this membrane may be superior to other pervaporation membranes used for butanol separation. Some of the details of use of this system with product recovery have been given in Section X(C) (Fed-batch fermentation) where 155 g L^{-1} ABE was produced in the integrated fermentation and product recovery process as compared to $<20 \text{ g L}^{-1}$ in a batch process. This membrane was so efficient that a butanol concentration up to 700 g L^{-1} was achieved in the permeate. It should be noted that a butanol solution above 78 g L^{-1} separates into two phases known as organic phase and aqueous phase. The organic phase (top layer containing over 700 g L^{-1} butanol) can be separated from the aqueous phase easily by decanting off. The bottom phase that contains 78 g L^{-1} butanol can be recycled to the pervaporation separation unit to concentrate it further.

While a significant amount of progress has been made to separate butanol from fermentation broth, cost of membrane still remains a prohibitive factor. A number of years ago it was found that the cost of a silicone membrane was $\$75 \text{ m}^{-2}$ with butanol selectivity of 30–40. At that stage it was projected that a silicalite membrane would be several times expensive than the silicone membrane. It should also be noted that butanol flux through a silicone membrane is of the order of $10\text{--}12 \text{ g}^{-2} \text{ h}^{-1}$ at a feed butanol concentration of $8\text{--}10 \text{ g L}^{-1}$. Such a low flux would require a huge pervaporation section thus adding to the capital cost of the process. Another factor that is important to the process is lifespan of a pervaporation membrane. The author of this article has an extensive experience in pervaporation. It is anticipated that the working life of a pervaporation membrane may not exceed 3 years.

Vacuum Recovery

Recovery of ABE by applying vacuum to the reactor is one of the more simple recovery techniques. In this process, the volatiles boil at fermentation temperature, thus generating vapors of the desirable volatile products or components. Then, these vapors are sent to a condenser where they are condensed followed by removing them as liquid. In comparison to pervaporation where a membrane and vacuum are required, this process eliminates the need for the membrane. Recovery of alcohols by this process was applied to remove ABE from the actual fermentation broth of *C. beijerinckii* P260. This process is also characterized by two factors known as selectivity of volatiles, and the rate of recovery ($\text{g L}^{-1} \text{ h}^{-1}$). The rate of recovery by vacuum can be as high as $10\text{--}15 \text{ g L}^{-1} \text{ h}^{-1}$, which is 25–40 times that of recovery rate by gas stripping, usually $0.35 \text{ g L}^{-1} \text{ h}^{-1}$. With such a high rate of recovery, this technique can also be integrated with the highly productive reactors where productivities of the order of $4.5\text{--}17 \text{ g L}^{-1} \text{ h}^{-1}$ are obtained.

Liquid CO₂ Extraction

Liquid CO₂ extraction is another technique that can be used to remove ABE from fermentation broth. Since CO₂ is inexpensive, its use for the extraction of butanol/ABE from a model butanol and ABE solutions was explored. The recovery was performed at 35°C and 10.34 MPa pressure and at these conditions a high separation efficiency (selectivity) was obtained from a feed solution containing 20 g L^{-1} butanol. Although, an economic evaluation of butanol recovery using this technique has not been performed, it is anticipated that this can be a potential technique for this process.

A comparison of various product recovery systems are listed in Table 4.

Use of Novel Substrates in Combination With Novel Technologies (Efficient Pretreatment, Hydrolysis, Fermentation, and Product Recovery Technologies)

In our economic studies, it was identified that substrate cost is one of the most important factors that influence butanol price significantly, thus indicating that more economical substrates be used for this valuable fermentation. As a result of this indication,

Table 4 A comparison of AB production using various product recovery systems

Recovery system	Reactor system	Cumulative ABE production (g L^{-1})	Sugar used (g L^{-1})
None (control)	Batch	20–33	60–80
Adsorption	Fed-batch	387.3	1198.5
Extraction	Fed-batch	23.8	68.6
Pervaporation	Fed-batch	165.1	307.2
Gas stripping	Fed-batch	233.4	500.0
	Continuous	460.0	1163.0

and numerous others, it has been primary focus of our laboratory (United States Department of Agriculture (USDA), National Center for Agricultural Utilization Research (NCAUR), Peoria, IL, United States) to use agricultural residues such as corn fiber, corn fiber xylan, wheat, and barley straws, corn stover, sweet sorghum bagasse (SSB) and energy crops such as switchgrass, for the production of biofuels such as ethanol, butanol and other chemicals. The reader is advised that fermentation of these substrates is a challenging task as they require pretreatment and hydrolysis prior to fermentation. During pretreatment, inhibitors are often formed that inhibit cell growth and fermentation. Studies on CFH fermentation to butanol revealed that CFH contained inhibitors that inhibited cell growth of *C. beijerinckii* BA101 and fermentation. Fermentation of treated CFH with XAD resin to remove fermentation inhibitors was partially successful.

Next, we investigated use of WS to produce ABE. As stated above pretreatment and hydrolysis of WS to simple sugars is essential prior to producing ABE. In our studies WS was hydrolyzed to simple sugars (hexoses and pentoses) using dilute acid pretreatment and enzymatic hydrolysis. The hydrolysate so obtained was successfully used to produce ABE without any treatment (to remove inhibitors) of the hydrolysate to remove fermentation inhibitors. Rather the hydrolysate was fermented vigorously and there were no signs of inhibition caused by hydrolysis inhibitors. These studies (hydrolysis and fermentation) were conducted in separate reactors (hydrolysis, fermentation, and recovery). Furthermore, WS pretreatment, hydrolysis, fermentation, and product recovery were combined in a single step and the studies were successfully completed.

These studies were also applied to the production of butanol from corn stover (CS). Of the 86 g L⁻¹ CS, over 97% of the sugars were released during the hydrolysis process and fermented completely to butanol (ABE). During the pretreatment and hydrolysis, acetic acid was also released from the hemicellulose, which was also converted to AB. The reader is advised that butanol producing cultures can utilize both hexose and pentose sugars obtained from the hydrolysates. The studies on production of solvents from cellulosic and hemicellulosic sugars were performed in a single reactor using *C. beijerinckii* P260. In this system the four technologies namely pretreatment, hydrolysis, fermentation, and product recovery were combined into a single process. These studies represent a major breakthrough on the conversion of cellulosic biomass to butanol. Furthermore, a process of simultaneous saccharification (starch to glucose), fermentation, and recovery was applied to food waste. In the above processes ABE were simultaneously removed by applying vacuum to the reactor. Followed by ABE removal as vapors, these solvents were recovered as liquid by condensation in a condenser.

Solution to the AB Problems: Where Are We Now?

It can be stated that solutions to some of the problems associated with butanol fermentation have been investigated. In early 1980s reactor productivities higher than 0.20–0.50 g L⁻¹ h⁻¹ were not possible. Development of continuous immobilized cell reactors and cell recycle reactors have resulted in much higher reactor productivities (4.5–15.8 g L⁻¹ h⁻¹) which would reduce the size and operational cost of the reactor substantially. Additionally, solvent yield has been improved as a result of combining production and recovery. In these systems, acids (acetic and butyric acids: reaction intermediates or metabolic by-products) cannot leave the reactor until they are converted into the final product. In traditional systems, ABE yield of 0.30–0.33 have been reported while in continuous integrated reactors yields of the order of 0.40–0.42 have been achieved.

With the advancement in technology, it has become possible to produce solvents from agricultural residues such as wheat straw, barley straw, corn fiber, corn stover, food waste, SSB and domestic waste. Production of solvents from LCS, SLCS, and whey permeate has also been successful. It should be noted that some years ago use of some of these substrates was not considered possible. Use of these substrates, novel hydrolytic enzymes, and combination of pretreatment, hydrolysis, fermentation, and recovery technologies has made this fermentation attractive as compared to butanol obtained from petrochemicals. Also application of in-situ product recovery technologies has allowed the use of concentrated sugar solutions. Sugar solutions containing sugar at 250–700 g L⁻¹ have been used in fed-batch reactors successfully. This has resulted in reduced size of various streams associated with solvent production.

Economic Scenarios

Economics of Butanol Production

During the last two decades a number of economic studies have been performed on the production of butanol from corn, whey permeate, molasses, and wheat straw. In these studies it has been determined that distillative recovery of butanol from fermentation broth is not economical as compared to butanol derived from petrochemicals (current route). It has also been identified that new developments in process technology (energy efficient pretreatment of cellulosic feedstocks, continuous reactor design, product recovery, use of concentrated sugar solutions for fermentation, recycle of water, use of H₂ as an energy source produced during fermentation, credit for CO₂ and waste biomass) for butanol production from renewable substrates would allow for a significant reduction in the price of butanol. The price of butanol derived from corn also depends upon the co-products credit which is significant.

To bring fermentatively derived butanol closer to commercialization and compete with petrochemically derived butanol, it is suggested that further research be focused on the development of superior cultures (as compared to the existing strains: *C. beijerinckii* BA101, *C. acetobutylicum* PJC4BK, and *C. beijerinckii* P260). These cultures produce total ABE on the order of 20–33 g L⁻¹. Further improvements in ABE yield, which is 0.40–0.42 when using *C. beijerinckii* BA101 or *C. beijerinckii* P260, should also be examined.

Other cultures have been reported to result in a product yield of approximately 0.30. Material balance suggests that approximately 53% of carbon is lost as CO_2 , indicating that only 47% of the carbon (from substrate) is directed for the product conversion.

Another problem with the butanol fermentation is the inability of these cultures to ferment hydrolysates of corn fiber, corn stover, barley straw, sugarcane bagasse, and switchgrass without inhibitor removal. In order to meet these challenges, new strains capable of utilizing agricultural biomass hydrolysates should be developed. Alternately, economic methods capable of removing inhibitors from the hydrolysates should be developed or novel pretreatment methods that do not produce inhibitors should be developed. It should be noted that use of wheat straw and corn stover has been a major breakthrough in the fermentation of cellulosic biomass to butanol. It is anticipated that hydrolyzed corn stalks, rice husk, and some of the energy crops such as switchgrass and miscanthus would be utilized without any inhibitor removal. In case of WS and CS simultaneous saccharification, fermentation, and recovery have been possible.

Conclusions

The production of butanol via the fermentation route is a relatively complicated process because the solventogenic clostridia are obligate anaerobes and the fermentation product (butanol) is toxic to the producing cultures. The possibility of incorporating in-line product recovery processes such as liquid–liquid extraction, perstraction, pervaporation, gas stripping, vacuum fermentation, and liquid CO_2 extraction, has generated a significant amount of interest. Simultaneous butanol fermentation and recovery has dramatically improved the productivity of butanol production from corn, wheat straw and corn stover (pretreatment, hydrolysis, fermentation, and recovery in case of WS and CS). By employing in-line recovery systems during butanol fermentation, substrate inhibition (due to high substrate concentration) and butanol toxicity to the culture are drastically reduced. Given that butanol is an

excellent potential fuel and the United States is rich in biomass, butanol production from corn and agricultural biomass has a promising future. As it is seen at this stage, the technology of butanol production from agricultural substrates such as WS, BS, CS, SSB, LCS, and SLCS appears to be ready for scale-up; however this also depends upon the fluctuations in crude oil prices. It should be noted that over last many years reactor productivity has been improved significantly. Fluidized bed reactors offer high productivity (Fig. 6) and can be integrated with product recovery. In these reactors size of cell-mass particles was increased by many fold (Fig. 7), thus improving reactor productivity dramatically. Novel advancements such as pretreatment, simultaneous hydrolysis, fermentation, and product recovery technologies (adsorption, gas stripping, pervaporation to some extent, and vacuum fermentation) appear to be ready for this challenging fermentation.

Glossary

Chemotaxis The movement along a chemical concentration gradient either toward or away from a chemical stimulus.

Commensal An organism participating in a relationship in which that species derives benefit while the other is unaffected.

Microbiome The entourage of associated microflora in a host.

Parasite An organism participating in a relationship in which that species derives benefit while the other is harmed.

Pathogenesis The process by which a disease occurs.

Saprophyte An organism that grows on and derives its nourishment from dead or decaying organic matter.

Symbiont An organism participating in a relationship in which both species derive benefit.

Overview

The spirochetes form one of the major Phyla of the Kingdom of Eubacteria. The depth of the spirochetal branch of the bacterial tree of life is indicated by the fact that Phylum *Spirochaetes* has a single Class, and a single Order. As shown in Fig. 1, the Order *Spirochaetales* is separated into three families, *Spirochaetaceae*, *Serpulinaceae*, and *Leptospiraceae*. The first family, *Spirochaetaceae*, includes a complex group of organisms that have adapted to diverse niches. At one extreme, there are a large number of free-living *Spirochaeta* organisms that can be cultivated from virtually any moist, nutrient rich environment. At the other extreme is the obligate parasite, *Treponema pallidum*, which relies on the activities of a single animal host, man, for its survival and dissemination. In between these two extremes are the commensal, parasitic, and symbiotic organisms with life cycles involving insects, animals, or both. The second family, *Serpulinaceae*, contains a single Genus, *Brachyspira*, and a more narrowly focused life-style involving residence in the lower intestinal tracts of animals. The third family, *Leptospiraceae*, includes both environmental saprophytes (e.g., *Leptospira biflexa*) and animal parasites (e.g., *Leptospira interrogans*) that cycle between bodies of fresh water and their preferred reservoir host.

Comparison of genome sizes indicates that life outside the host is much more genetically challenging than a life of host dependence. Free-living organisms such as *Spirochaeta aurantia* and *L. biflexa* have relatively large genomes relative to *E. coli* (Fig. 2). In contrast, adaptation of spirochetes to a commensal or parasitic lifestyle has resulted in genomic contraction. For example, while *L. borgpetersenii* and *L. interrogans* evolved from a common ancestor that had the ability to survive both in nature and in the mammalian host, *L. borgpetersenii* has become an obligate parasite of cattle that requires direct transmission for animal to animal. As a result, the *L. borgpetersenii* genome has become 16% smaller and remains in a process of decay with 12% of its genes as nonfunctional pseudogenes. *Treponema denticola* has an intermediate-sized genome, perhaps related to the fact that although it is found only in animal hosts, it competes for nutrients in the complex oral microbial community. The *Borrelia* spp. and *T. pallidum* have the smallest genomes, with chromosomes only 1 Mb in size, which is consistent with their host dependence and lack of a free-living phase of their life cycle.

Spirochetes are defined by their unique morphology and rotational motility. Most spirochetes are helical coils—the one exception being *Borrelia burgdorferi*, which is actually a flat-wave. Spirochetes are expert swimmers that are entertaining to watch by dark-field microscopy. In low viscosity liquids, spirochetes appear to spin in place. Increasing the viscosity by addition of methylcellulose allows spirochetes to bore through the medium at a high rate of speed. The observer is quickly led to an understanding of how their screw-like movements would impart invasive properties to spirochetal pathogens. The organs of motility are flagella anchored near each end of the cell. Spirochete flagella are sometimes referred to as “endoflagella” because they are subsurface structures, wrapping around the protoplasmic cell cylinder, as shown in Fig. 3, instead of extending out beyond the surface of the cell as in all other flagellated bacteria. In at least one case, spirochete flagella also determine cell shape. *B. burgdorferi* mutants lacking the FlaB flagellar filament protein are rod-shaped rather than wave. Spirochetes differ in flagellar number and length. *Leptospira* have a single flagellum at each end of the cell that extends only a short distance along the length of the cell. In contrast, *Cristispira* spp. have bundles of over a 100 flagella at each end.

Chemotaxis allows bacteria to swim toward attractants such as nutrients and away from repellants by controlling the rotational direction of the flagellar motor. Flagella can rotate in a clockwise or counterclockwise direction. Sensory proteins called methyl-

Fig. 1 Taxonomic organization of the spirochetes. Three families of spirochetes have been defined. Family Spirochaetaceae includes the free-living *Spirochaeta* spp., the parasitic *Borrelia*, and the commensal, parasitic, and symbiotic *Treponema* spp. Family Serpulinaceae are bacteria that colonize the lower intestinal tracts of mammals. Family Leptospiraceae includes both free-living nonpathogens and organisms that are able to invade animal reservoir hosts.

Fig. 2 Comparative genome sizes of spirochetes. Free living spirochetes including *Leptospira* and *Spirochaeta* spp. have genomes that rival the size of *E. coli*. Host dependent spirochetes such as *T. pallidum* and *Borrelia* spp. have some of the smallest known genome sizes. Treponemes that live in the complex environments of the oral cavity (*T. denticola*) and termite gut (*T. azotonutricum*) have intermediate-sized genomes.

Fig. 3 Spirochetal architecture. Spirochetes share a unique structure and motility strategy in which the endoflagella are inserted at opposite poles and wrap around the protoplasmic cylinder. (A) Electron micrograph of *Leptospira* showing a single endoflagellum at one end of the cell. (B) Schematic diagram showing endoflagellar location relative to the outer membrane and cell wall. Reproduced from Holt, S. M. (1978). *Anatomy and chemistry of spirochetes*. Microbiological Reviews 42, 114–160.

accepting chemotaxis proteins (MCPs) control the directional switch in the flagellar motor. Clockwise rotation causes a cell to tumble (stop), counterclockwise rotation causes a cell to run (go). Spirochetes are unique in having flagella at each end. Effective spirochete movement involves flagellar rotation in the counterclockwise direction at the leading end and in the clockwise rotation at the trailing end. If the flagella at alternate ends are rotating in the same direction, spirochetes will flex in place rather than spin. It is not known how spirochetes coordinate the flagella at their alternate ends, or how MCPs orient spirochete movement. In any case, spirochetes are clearly adept at chemotaxis. For example, *B. burgdorferi* are able to find their way into a capillary tube containing *N*-acetyl glucosamine, a sugar required for cell wall biosynthesis. Sensory proteins are not only used for chemotaxis but also for regulation of gene expression. Spirochetes vary widely in terms of the number of sensory proteins they have. As mentioned previously, life outside the host is challenging and “extroverts” (organisms with a free-living stage) have far more sensory proteins than “introverts” that never leave the host. For example, *L. interrogans*, which lives both inside and outside a mammalian host has 10 times the number of sensory proteins as *T. pallidum*, an obligate human parasite. Fig. 4 shows the correlation between life-style and numbers of sensory proteins.

The unique spirochetal architecture has both gram-negative and gram-positive features. Like gram-negative bacteria, spirochetes are “diderms,” or double-membrane bacteria. However, the spirochetal outer membrane is much more fluid and labile than the outer membrane of gram-negative organisms. In typical enteric gram-negative bacteria, the outer membrane is supported by, and closely associated with, the underlying peptidoglycan cell wall. In contrast, the spirochetal cell wall is more closely associated with the inner, or cytoplasmic membrane than the outer membrane (Fig. 5), a feature of gram-positive bacteria. Another important difference between the outer membranes of most Gram-negative bacteria and those of treponemes and borreliae is a lack of lipopolysaccharide (LPS). Leptospirae have LPS, but there are significant structural differences between leptospiral and *E. coli* LPS such that human toll-like receptor 4 is unable to bind to leptospiral LPS. The lack of recognizable LPS allows spirochetes to function as “stealth pathogens” that are able to invade and persist in the bloodstream and tissues of the body without detection by the early warning system of innate immunity.

Protein export pathways of spirochetes resemble those of other bacteria. The Sec pathway for exporting proteins with signal peptides across the cytoplasmic membrane is conserved. Genes encoding enzymes that process signal peptides are present in spirochete genomes but their specificities are clearly unique because prediction algorithms such as Psort and LipoP frequently do not apply to spirochetal signal peptides. Computer recognition of signal peptides of spirochetal lipoproteins requires development of spirochete-specific approaches such as the SpLip algorithm. Upon reaching the periplasmic face of the cytoplasmic membrane,

Fig. 4 Comparison of spirochetal life styles and sensory transduction genes. Spirochetes have a wide variety of sensory transduction genes including histidine kinase sensors (HisK), methyl-accepting chemotaxis proteins (MCP), etc. (see Galperin, BMC Microbiology 2005; 5:35 for further definitions). Spirochete “extroverts” that live outside the host have a much greater number of sensory transduction proteins per genome than host dependent “introverts.”

Fig. 5 Spirochete cross-section. Elements of spirochetal architecture include (A) outer membrane; (B) Periplasm; (C and D) Peptidoglycan cell wall; (E) Cytoplasmic membrane; (F) Cytoplasm; (G) Nuclear material; and (H) Endoflagella. Note that the endoflagella are subsurface structures and that the cell wall is more closely associated with the cytoplasmic membrane than the outer membrane. Reproduced from Holt, S. M. (1978). Anatomy and chemistry of spirochetes. Microbiological Reviews 42, 114–160.

spirochetal lipoproteins are shuttled to the outer membrane via the Lol pathway. Here again, rules that apply for *E. coli* lipoproteins have been altered for spirochetal lipoproteins such that retention of spirochetal lipoproteins in the cytoplasmic membrane involves negatively charged amino acids after the amino-terminal cysteine and export to the outer membrane is by default. Membrane fractionation and ultrastructure studies demonstrate three types of spirochetal outer membrane proteins: transmembrane porin-like molecules, lipoproteins, and peripheral (nonintegral) membrane proteins. All spirochetes have Omp85 (also known as BamA) and TamB homologs for assembly and insertion of outer membrane proteins (Omps). Transmembrane Omps are required for transport functions and both transmembrane and surface lipoprotein Omps have been shown to be involved in host-pathogen interactions.

Treponema

The Genus *Treponema* includes a broad diversity of parasitic and commensal species, most of which exist in complex bacterial communities. A notable exception is highly invasive obligate human pathogen, *Treponema pallidum*, subspecies *pallidum*, the agent of syphilis. *T. pallidum*, syphilis, and its history are covered of separate chapters in this *Reference Module*. In passing, it should be mentioned that *T. pallidum* has two other subspecies and a sister species that cause nonvenereal skin infections of humans (see Fig. 1). *T. pallidum* subspecies *pertenue* causes yaws, *T. pallidum* subspecies *endemicum* causes endemic syphilis (bejel), and *T. carateum* causes pinta. Another member of this species group is *T. paraluisccuniculi*, the agent of venereal spirochetosis of rabbits, which has an overall genome sequence similarity of 98.6–99.3% with *T. pallidum* spp. *pallidum*. It should also be mentioned that a number of additional *Treponema* species have been isolated from the intestinal tracts of animals including cows (*T. bryantii* and *T. saccharophilum*) and pigs (*T. succinifaciens*). In this section, we will cover the oral treponemes, the organisms that cause papillomatous digital dermatitis of cattle, and the termite gut treponemes involved in the digestion of cellulose.

Oral Treponemes

Oral treponemes were some of the first bacteria described in the writings and drawings of Antonie van Leeuwenhoek, the Father of Microbiology. In 1676, when examining a dental plaque from the mouth of an old man, van Leeuwenhoek found “an unbelievably great company of living animalcules, a-swimming more nimbly than any I had ever seen up to this time. The biggest sort. . . bent their body into curves in going forwards. . .” Today, anyone with a dark-field microscope can repeat van Leeuwenhoek’s experiment. If the sample is taken from the periodontal space (located between the tooth and the gum) of a patient with gum disease, it is likely that spirochetes will be observed to be the predominant bacterial forms. A remarkable diversity of oral treponeme morphologies is present in the mouth, with a broad variety of diameters, lengths, wavelengths, amplitudes, and numbers of endoflagellae. Sizes range from 0.1 to 0.4 μm in diameter and 5–20 μm in length.

The microbial community of the mouth, referred to as the oral “microbiome,” is estimated to include upwards of 500 different bacterial species. Given the complex environment in which they live, it is not surprising that it has been relatively difficult to isolate and cultivate oral treponemes. Like most bacteria that live in the periodontal space, most oral treponemes are strict anaerobes. However, some treponemes, such as *T. denticola*, can tolerate low concentrations of oxygen. Treponemes are intrinsically resistant to rifampin, which makes it possible to use rifampin-containing culture medium to exclude other bacteria and select for treponemes. More than 10 species of oral treponemes have been isolated, allowing more detailed studies of their morphologies and metabolic requirements. More detailed enumeration of oral treponeme diversity has become available through microbiome studies. In one comparison of healthy and periodontitis subjects, five novel treponemal species were found for every one that had been cultivated. Nearly 25% (49/215) of the new oral bacterial species discovered were treponemes! Based on these molecular studies, 10 phylogenetic groups of human oral treponemes in two clusters have been defined (Fig. 6). One of these clusters also contains treponemes associated with bovine digital dermatitis (see below), while the other cluster contains intestinal treponemes of cattle and swine.

Several lines of evidence implicate treponemes as oral pathogens. Although treponemes can be found in small numbers in the mouths of healthy individuals, their numbers and diversity are strongly correlated with the severity of chronic and aggressive forms of periodontitis and their numbers are diminished with clinical treatment. Two species that have been associated with periodontitis are *Treponema denticola* and *Treponema lecithinolyticum*. Both gingivitis and periodontitis are extremely common inflammatory gum diseases. The distinction is that while gingivitis is reversible, periodontitis involves erosion of the dental ligament that attaches the tooth to the supporting bone at the base of the periodontal pocket (Fig. 7). Periodontitis affects 50% of the US population over 30 years of age and is the leading cause of tooth loss. While treponemes are typically found at the base of the periodontal pocket in association with other pathogenic organisms, such as *Porphyromonas gingivalis* and *Tannerella forsythia*, immunofluorescence microscopy shows that the treponemes the most invasive organisms, typically invading the epithelial cells at the leading edge of invasion process. Treponemes also appear to be involved in endodontal (root canal) infections; *Treponema maltophilum* DNA was detected in 50% of root canal samples using 16S rDNA-based PCR methods.

Several pathogenetic mechanisms have been identified by which oral treponemes cause disease. By virtue of their motility, chemotaxis, and narrow diameter, spirochetes are able to slip between epithelial cells and invade the subepithelial layers of the gum tissue. Although treponemes do not make Gram-negative lipopolysaccharides, they do elaborate a variety of glycolipids and lipoproteins that stimulate innate inflammatory pathways. *T. denticola* expresses a serine protease, dentilisin, that digests host extracellular matrix proteins including fibronectin, laminin, and fibrinogen. Dentilisin activates host matrix metalloproteinases, and together with dentilisin these enzymes serve to alter and eventually degrade the barriers that prevent invasion by other periodontal bacteria. Exposure to *T. denticola* causes cytoskeletal rearrangements that disrupt normal host cells functions. These cytotoxic effects are probably caused by *T. denticola* release of Msp, the major sheath protein. Msp is a porin-like molecule that appears to insert into host cell membranes and trigger intracellular calcium fluxes, which are thought to damage epithelial cell barriers and impair clearance of invaded bacteria by polymorphonuclear leukocytes.

Fig. 6 Phylogenetic tree of the treponemes. Comparison of treponeme 16S rRNA sequences shows segregation into three relatedness clusters: Two clusters of oral treponemes and a cluster of termite gut treponemes. Note that *T. pallidum*, the agent of syphilis is related to the first cluster of oral treponemes.

Papillomatous Digital Dermatitis Treponemes

Papillomatous digital dermatitis, or PDD, is a polymicrobial infection of the soft tissue adjacent to the hoofs of cattle. Affected animals have painful ulcers referred to as heel warts or footwarts. Since it was first described in the 1970s, PDD has spread throughout the world, including most herds in the United States, and is now the leading cause of lameness in dairy cattle. The spread of PDD is related to industrial-scale dairy practices where cattle are continuously kept in barns or feedlots on moist surfaces and not allowed to graze. Cultures of PDD lesions show a mixed population of anaerobic bacteria including a number of spirochetes that are closely related to oral treponemes such as *T. denticola*, *T. medium*, and *T. vincentii* found in Treponema cluster 1 (Fig. 6). Immunofluorescence studies of biopsies of PDD lesions reveal invasion of treponemes into the soft tissues of foot, not unlike the invasion of treponemes observed in the periodontium of the mouth.

Termite Gut Treponemes

Diversity

Although the volume of the termite hindgut can be as small as 1 μ L, the diversity of treponemal phylotypes and morphotypes within a single termite is staggering. Microscopy of the termite hindgut contents reveals treponemes ranging from 0.1 to 1 μ m in diameter and 3–100 μ m in length, with a variety of cell wavelengths and amplitudes (Fig. 8). Some of the larger forms can have 100

Fig. 7 Schematic representation of health, gingivitis and periodontitis. The periodontal pocket depth (PD) is increased in gingivitis due to tissue swelling associated with inflammation. In periodontitis the PD is further increased due to the loss of the tissue attachment to the root of the tooth (AL: attachment loss). Periodontitis is further characterized by loss of supporting alveolar bone. Treponemes are typically found at the base of the periodontal pocket. Reproduced from Kinder-Haake, S. et al. (2006). Periodontal diseases, In: Lamont et al. (eds) Oral Microbiology & Immunology. ISBN-13: 9781555812621.

Fig. 8 Phase contrast micrograph of termite gut treponemes. A variety of treponeme sizes and morphologies are present in the termite gut. Note the treponemal appendages attached to the hypermastigote protozoan, *Trichonympha agilis*. Reproduced from Breznak, J. A. (2006). In Radolf, J. D. and Lukehart, S. A. (eds.) Pathogenic Treponema: Molecular and Cellular Biology. ISBN: 1-904455-10-7.

or more periplasmic flagella. Many termite gut treponemes are individual cells, while others are ectosymbionts of protozoa, functioning as their motility organelles. Recent metagenomic analysis of the total hindgut microbiota of arboreal wood-feeding *Nasutitermes* termites revealed that 68% of the genetic material was treponemal in origin. As many as a hundred *Treponema* species can be present within the digestive tract of a single termite species. These termite treponemes form a distinct cluster within the treponeme phylogenetic tree (Fig. 6). In addition to several named species, 10 termite *Treponema* groups have been defined. The *Spirochaeta* species, *S. stenostrepta* and *S. caldaria*, were isolated from water as free-living organisms and named before their 16S sequences were known, but fall within the termite treponeme cluster and should be considered *Treponema* species likely to have been released from animals or insects.

Metabolism

Termite gut treponemes are symbionts, benefitting their termite hosts by contributing to the digestion of woody plant material. Like most host-dependent spirochetes, termite gut treponemes were difficult to isolate. Eventually, the first termite gut treponemes to be grown in pure culture were isolated from the California dampwood termite, *Zootermopsis angusticollis*, and assigned to the new

species, *T. primitia*. *T. primitia* is an anaerobe, and was grown in sealed containers. In the process of working with the *T. primitia* cultures, it was discovered that a vacuum had developed in the headspace of the *T. primitia* cultures. This observation led to the finding that *T. primitia* could convert H_2 and CO_2 gases to acetate. Acetate was known to be a major source of energy and carbon for termites. The treponemes were found to reduce single carbon CO_2 to two-carbon acetate molecules via a well-known acetyl-CoA pathway, thus providing nutrients to the termite that would otherwise have escaped in a gaseous form.

Treponemes were subsequently found to benefit termite metabolism in other ways. Cellulose is high in energy but relatively poor in nitrogen required for formation of amino acids. A second species, the aptly named *T. azotonutricum*, was found to be able to convert significant amounts of atmospheric N_2 to ammonium using its unique dinitrogenase reductase activity. Until recently, it was not known to what extent termite gut treponemes participated in other aspects of wood polysaccharide digestion. Termite treponeme enzymes have now been shown to cleave aromatic ring compounds of lignan, the most difficult component of wood to metabolize. Eventually, it is hoped that the highly evolved digestive abilities of termite treponemes can be harnessed to convert woody biomass to green energy.

Borreliae

Morphology and Metabolism

Borrelia spp. are separated into two large genetic groups: the relapsing fever (RF) borreliae and the Lyme disease (LD)-related borreliae. This chapter covers the RF borreliae. The LD borreliae are covered in a separate chapter of this *Reference Module*. Borreliae vary from 8 to 30 μm in length and 0.2–0.5 μm in width, with the RF borreliae tending to be shorter and wider than the LD-related borreliae. Borreliae exhibit the unique rotational motility of spirochetes powered by endoflagella. The RF borreliae have 15–30 endoflagella while the LD-related borreliae have 7–11 endoflagella. Unlike the endoflagella of other spirochetes, the endoflagellae of borreliae lack sheaths. The other distinguishing morphological characteristic of the borreliae is the lack of cytoplasmic tubules.

Borreliae are obligate parasites with a life cycle that alternates between arthropod vectors and mammalian hosts. Despite their host dependence and small genome size, many *Borrelia* spp. have been cultivated using nutritionally rich media, similar to tissue culture media, including many amino acids, vitamins, and rabbit serum. Unlike other bacteria, borreliae do not require iron and lack most of the iron-dependent enzymes in their genome. Glucose is required and is metabolized via the Embden-Meyerhof glycolytic pathway, but borreliae lack TCA cycle, and ATP production solely relies on the substrate phosphorylation. Borreliae also lack the pyruvate dehydrogenase complex to synthesize acetyl-coA from pyruvate, rather using acetate to produce the essential acetyl-coA with the AckA-Pta pathway. Borreliae require exogenous *N*-acetylglucosamine for cell wall synthesis, presumably because this chitin component is constitutively available in ticks. In addition, borreliae have the glycerol uptake and metabolic pathway to utilize glycerol as an alternative carbon source, which appears to be important for borreliae to survive in ticks. Relapsing fever borreliae have an extra gene that is absent in Lyme disease borreliae, *glpQ*. *glpQ* encodes glycerophosphodiester phosphodiesterase that allows hydrolysis of deacylated phospholipids to glycerol-3-phosphate, which may contribute to the high cell density of RF borreliae but not LD borreliae in patients' peripheral blood. Components in commercial Bovine serum albumin (BSA) fraction V is provided as a source of long-chain fatty acids for membrane biosynthesis. The bane of borrelial researchers is the variable ability of different lots of BSA (as well as rabbit serum) to support borrelial growth. Although borreliae make superoxide dismutase but lack catalase, they are oxygen sensitive and can only tolerate low levels of oxygen. One possible explanation for lot to lot variability of BSA is that polyunsaturated fatty acids supplied by certain lots of BSA appear to be the target of reactive oxygen species (ROS), resulting in damage to borrelial membranes.

Epidemiology and Phylogeny

The borrelial life cycle involves alternating parasitism of arthropod vectors and mammalian hosts. The aptly named *Borrelia recurrentis* is the only one of the RF *Borrelia* transmitted by the human body louse (*Pediculus humanus*) and is historically the most important of the RF borreliae. Numerous plagues of RF have been recorded, going back at least as far as the time of Hippocrates. Associations with war, famine, and displaced populations resulting in poverty and overcrowding were well known, but the specific association with body lice was not recognized until 1907. The 20th century witnessed devastating epidemics of louse-borne RF (LBRF). In the aftermath of the Russian revolution, there were 13 million cases of LBRF in Russia and Eastern Europe, resulting in 5 million deaths. Because humans are the only mammalian host of LBRF and its vector, outbreaks can be effectively aborted by treatment of clothes and bed linens with insecticides or simply by heating to at least 55 °C (130 °F) for 5 min. LBRF has been eradicated everywhere except for isolated areas of Ethiopia and neighboring countries involved in war (Sudan, Eritrea, and Somalia).

Aside from *B. recurrentis*, all other RF borreliae are transmitted by ticks and have nonhuman animal host reservoirs. These tick-borne forms of RF are considered endemic zoonoses and are found worldwide. Most (but not all!) borreliae causing tick-borne relapsing fever (TBRF) are transmitted by the *Argasidae* family of soft-body ticks, while the LD-related borreliae are transmitted by the *Ixodidae* family of hard-body ticks. Because of the close relationship between TBRF borreliae species and their tick vectors, the names of the *Borrelia* species derive from the species of tick vectors that transmit them: *B. hermsii* is transmitted by *Ornithodoros hermsi*, *B. parkeri* is transmitted by *Ornithodoros parkeri*.

The distinction between different types of ticks is important because their different feeding strategies dictate the circumstances under which humans are likely to encounter the borreliae they carry. Soft-body ticks are nocturnal feeders that seek out sleeping animals by following carbon dioxide and temperature gradients. Although large in size, they have a painless bite and their soft bodies have a distensible stomach that allows them to feed rapidly (15–90 min), drop off, and disappear before being recognized. The large blood meal allows soft body ticks to live for up to 15 years between feedings, while retaining viable borreliae in their midgut. *Ornithodoros* species of soft body ticks may transmit borreliae to their progeny, a process referred to as “transovarial transmission.” The frequency of transovarial transmission of borreliae to tick progeny varies greatly between tick species. The frequency of transovarial transmission is high in *O. turicata*, low in *O. hermsi*, and does not occur in *O. parkeri*.

Hard-body ticks seek out their blood meal during the day and feed for longer periods of time (typically days). The smaller stomach size also requires more frequent feedings. Blood meals are required for a hard-body tick to mature from larvae to nymph, from nymph to adult, and then for the adult to reproduce. Hard-body ticks are mentioned here because there are two notable exceptions to the rule that TBRF Borrelia are transmitted by soft-body ticks: *B. miyamotoi* is transmitted by *Ixodes* species (wood ticks), and *B. lonestari* is transmitted by *Amblyomma americanum* (the lone star tick). In north America, the prevalence of *B. miyamotoi* in nymphal and adult *I. scapularis* ticks is 10-fold lower than that of the Lyme disease spirochetes. However, *B. miyamotoi* spirochetes are also present in host-seeking larval ticks as *B. miyamotoi* can infect ticks transovarially from adult ticks to their offspring, whereas *B. burgdorferi* must be acquired by larval ticks during a blood meal.

16S rRNA sequences of RF *Borrelia* spp. separate phylogenetically into three relatedness groups: Old World RF borreliae, New World TBRF borreliae, and the *B. hermsii*/*B. anserina* group (Fig. 9). *B. hermsii* is the most common agent of human TBRF in North America and is endemic to the coniferous forests of the western United States and southern British Columbia from 3000 to 9000 ft. in elevation. The incidence of TBRF peaks in July and August when vacationers visit rustic cabins in mountainous locations that are inaccessible during the winter. *B. hermsii* achieves high blood densities for prolonged periods of time in pine squirrels (*Tamiasciurus* spp.), which serves to facilitate transmission to other ticks. Chipmunks and some rodents may also become infected but with lower blood densities and for shorter periods of time than in pine squirrels. Two distinct genomic groups of *B. hermsii* have been described based on sequencing the intergenic spacer region between the 16S rRNA and *ileT* tRNA genes. The distribution of the two *B. hermsii* genomic groups overlap geographically, indicating that migratory animals, such as birds, may play a role in dissemination. *B. hermsii* has been found in the bloodstream of a dead owl, and is phylogenetically related to *B. anserina*, the agent of avian spirochetosis (Fig. 9).

Other New World TBRF *Borrelia* differ from *B. hermsii* in their geographical distribution. *B. turicatae* occurs in the southwestern United States and northern Mexico. TBRF outbreak of *B. turicatae* infection has been reported in Texas. *B. parkeri* isolates from ticks in the coastal regions of California and Baja California have been implicated as a cause of human disease, but the evidence is circumstantial. Recently, the 16S sequence of a related *Borrelia* species was obtained from the argasid bat tick, *Carios kelleyi*, from an attic in Iowa. There is the potential for human disease given the close phylogenetic relationship with human pathogens, the

Fig. 9 Phylogenetic tree of the relapsing fever borreliae. 16S rRNA sequences of Old World *Borrelia* spp., including *B. recurrentis*, the agent of louse-borne relapsing fever, cluster in the lower right section of the tree. Sequences of New World *Borrelia* spp. cluster in the upper section of the tree. Sequences from *B. hermsii* and the bird-associated *B. anserina* cluster in the lower left section of the tree.

cohabitation of *C. kelleyi* in homes and the willingness of *C. kelleyi* to feed on humans. *B. coriaceae* is transmitted by soft-body *Ornithodoros* ticks and its reservoir in North America is the black-tailed deer. Human infection with *B. coriaceae* has not been described, but it is thought to cause abortion in cattle. *B. mazzottii* and *B. venezuelensis* have been described in Central and South America, but their 16S rRNA sequences and relatedness to other New World TBRF borrelia are unknown.

Some New World TBRF species are transmitted by hard-body ticks. Like *B. burgdorferi*, *B. miyamotoi* is found in *Ixodes* ticks and *Peromyscus leucopus*, the white-footed mouse. *B. lonestari* is carried by *Amblyomma americanum*, the lone star tick, which is widely distributed in North America and known to transmit ehrlichiosis and tularemia. The ability of *B. lonestari* to infect humans is unknown. Among Old World TBRF borrelia, *B. duttonii* is the species that is genetically most similar to *B. recurrentis*, and they probably share a common ancestor. *B. duttonii* and the related species, *B. crocidurae*, are transmitted by soft-body ticks and are important causes of TBRF in Sub-Saharan Africa. A number of other Old World TBRF *Borrelia* have been described in the Middle East, the Caucasus, and Central Asia, but 16S rRNA sequences are available for only a couple of these species: *B. persica* and *B. hispanica*, found in Israel and Spain, respectively.

Molecular Pathogenesis and Disease

The molecular mechanisms of antigenic variation that are the hallmark of relapsing fever have been best described in *B. hermsii*. In the tick, the major *B. hermsii* surface protein is the variable tick protein, which is required for transmission to the mammalian host during tick feeding. In response to temperature changes during the blood meal, *B. hermsii* switches expression to the variable major protein (vmp) locus located on the expression plasmid. As the bacteria begin to reach high densities in the bloodstream of the infected animal, the host mounts an antibody response to the protein encoded by the gene in the vmp expression locus. Clearance of bacteria by vmp-specific antibody is eventually followed by emergence of bacteria that have undergone a recombinational event on the expression plasmid involving insertion of an alternate gene from the repertoire of vmp genes. It had long been observed that there was a bias toward a patterned sequence of vmp gene insertion events. An explanation for the pattern was provided by the upstream homology sequence (UHS) and downstream homology sequence (DHS) of the variable genes. The probability of a subsequent gene being inserted into the variable protein expression locus was related to the homology of its UHS with the gene currently in the locus and the distance from the end of the new gene to its DHS.

A programmed succession of surface proteins enables RF borreliae to repeatedly emerge at high levels in the bloodstream (Fig. 10). The ability to repeatedly emerge into the bloodstream is advantageous to the bacteria, because it favors acquisition by bloodfeeding arthropods. However, such a high density of bacteria is very hazardous to their animal host, because it evokes such an intense immune response to the foreign antigens. Bouts of LBRF and TBRF differ in their intensity and in the number of relapses. LBRF tends to recur less often, but the episodes are much more severe, with a mortality rate of 4–40%. After a typical incubation period of 7 days, patients experience sudden onset of fever, rigors, headache, muscle pain, and lethargy. In LBRF, most patients have liver and spleen enlargement, while cough and symptoms of meningitis are common. Nerve palsies, paralysis, seizures, and coma may occur in severe cases. The most common causes of death in LBRF are arrhythmias of the heart, brain hemorrhage, and liver failure. LBRF during pregnancy frequently results in miscarriage. The mortality rate in TBRF is typically much lower: 2–5%. Nevertheless, TBRF due to *B. turicata*, *B. duttonii*, and *B. crocidurae* are frequently associated with debilitating neurologic symptoms not seen with other forms of TBRF.

Fig. 10 Dark-field micrograph of blood containing relapsing fever borreliae. Variation in surface antigens enables relapsing fever borreliae to reach high levels in the bloodstream, often achieving densities as high as 10^6 – 10^7 bacteria per milliliter. Spirochetes appear as bright wavy forms while the red blood cells appear as fainter circles.

RF *Borrelia* are susceptible to a broad range of antibiotics. LBRF can be successfully treated with a single dose of tetracycline. Beta-lactam antibiotics such as penicillin are typically avoided in LBRF because they may result in the sudden lysis of large amounts of bacterial antigens, which can precipitate the Jarisch-Herxheimer reaction, a paradoxical worsening of symptoms with severe chills, fever, and potentially life-threatening shock. Patients should be observed for 2 h after initiation of antibiotics in case there is a need for resuscitation with intravenous fluids.

Brachyspira

Another major grouping within the order *Spirochaetales* are the *Brachyspira*, which are intestinal spirochetes classified within the family, *Serpulinaceae*. *Brachyspira* are large, loosely coiled spirochetes ranging in size from 2 to 13 μm in length, and 0.2–0.4 μm in width. *Brachyspira* are able to grow under strict anaerobic conditions, but small amounts of oxygen can increase growth efficiency. The *nox* gene, encoding NADH oxidase, is required for oxygen tolerance. Inactivation of the *nox* gene increases oxygen sensitivity 100-fold. *Brachyspira* are cultivated anaerobically on blood agar at 37 °C and selective media are typically used for primary isolation of organisms from stool specimens.

The *Brachyspira* have undergone a series of changes in nomenclature. The isolation of the swine dysentery agent was originally described in the early 1970s and referred to as "*Treponema hyodysenteriae*." In the 1990s, DNA-DNA hybridization and partial 16S sequence data indicated that the "*T. hyodysenteriae*" organism had little genetic relatedness to the treponemes and was assigned its own genus, *Serpula*, which was quickly reclassified *Serpulina* to avoid confusion with a previously named fungal genus. However, *Serpulina* eventually gave way to *Brachyspira* when it was realized that *S. hyodysenteriae* was related to *Brachyspira aalborgi*, which had been isolated from humans with intestinal spirochetosis in Aalborg, Denmark in the early 1980s. The prefix *Brachy-*, deriving from the Greek word for "short," was used as a descriptive term because the Danish isolates were only 2–6 μm in length.

B. hyodysenteriae is an important worldwide problem for the pig industry. Outbreaks with mortality rates of up to 50% occur in naïve herds. The infection is a true dysentery, causing inflammatory and hemorrhagic disease of the colon. *B. hyodysenteriae* is beta hemolytic on sheep blood agar and hemolysins are thought to be important virulence factors. The organism is difficult, but not impossible, to eradicate from farms. In Scandinavia, where the use of antibiotics is strictly controlled, few herds are infected by *B. hyodysenteriae*. In most countries, antibiotic supplementation of feed is used to suppress the *B. hyodysenteriae* problem, and infection rates are often over 30%. However, antibiotic resistance is growing and new strategies for prevention and control of *B. hyodysenteriae* infection are urgently needed.

The genus *Brachyspira* is now populated with a number of commensal and pathogenic species, which have been isolated from the intestinal tracts of a variety of animal hosts. Species with predilections for pigs, humans, and birds are clustered on a phylogenetic tree from their 16S sequences (Fig. 11). "*B. suanatina*" is the name proposed for an organism that is related to, but genetically distinct

Fig. 11 Phylogenetic tree of the *Brachyspira*. Relatedness tree of 16S rRNA sequences of *Brachyspira* spp., including *B. hyodysenteriae*, the agent of swine dysentery. *B. aalborgi* and *B. pilosicoli* cause intestinal spirochetosis in humans in developed and developing countries, respectively.

from, *B. hyodysenteriae* by 16S rRNA sequence analysis. *B. suanatina* has been isolated both from pigs and from mallard ducks, is beta hemolytic and can cause disease in experimentally infected pigs. *B. intermedia* is a third pig isolate found in the same genetic cluster with *B. hyodysenteriae* and *B. suanatina* and may cause disease under certain circumstances. Nondysenteric porcine diarrhea due to intestinal spirochetosis has been linked to *B. pilosicoli*, which has also been associated with disease in chickens and humans (see below). *B. innocens* and *B. murdochii* are considered to be commensals occasionally isolated from healthy pigs.

Brachyspira species are also important in the poultry industry. Diarrhea and egg production problems in chickens have been attributed to *B. alvinipulli*, *B. intermedia*, and *B. pilosicoli*. As in pigs, *B. innocens* and *B. murdochii*, and a third species, *B. pulli* appear to be nonpathogenic for chickens. Chronic watery diarrhea due to human intestinal spirochetosis (HIS) has been linked to two species, *B. aalborgi* and *B. pilosicoli*, with the latter being associated with intestinal disease in pigs and chickens. High prevalence rates of *B. pilosicoli* carriage have been found in aboriginal populations living in poor sanitary conditions with high levels of animal exposure. In contrast, *B. aalborgi* occurs more frequently in developed countries, typically in AIDS patients with chronic diarrhea. The pathogenic potential of *Brachyspira* spp. for humans is controversial. Biopsies show palisades of brachyspires lining the surface of colonic epithelial cells, which is likely to impair function (Fig. 12). *B. pilosicoli* is associated with watery diarrhea and has been isolated from the bloodstream of sick patients.

The genome sequences of several *Brachyspira* species have now been elucidated. Large numbers of proteases and hemolysins were identified in the *B. hyodysenteriae* genome as potential virulence factors. A surprising discovery was the finding of an *rfb* gene cluster on the 36 Kb circular plasmid of *B. hyodysenteriae*. Among *B. hyodysenteriae* strains, plasmid loss is associated with virulence attenuation. The most abundant outer membrane proteins of *B. hyodysenteriae* are the Vsp proteins, which are encoded by 7–10 paralogous genes per genome. Lack of significant sequence variability of vsp genes suggests that these genes are not used as a mechanism for antigenic variability. In fact, multiple Vsps are transcribed simultaneously and expressed as high molecular mass protein complexes. Vsps and other outer membrane proteins expressed during infection are of great interest as potential vaccines and serodiagnostic antigens.

Leptospira

Morphology and Metabolism

“*Leptospira*” derives from the Greek *leptos* (thin) and Latin *spira* (coiled). Aptly named, the leptospire is among the thinnest bacteria known: a mere 0.1 μm in diameter and 6–12 μm in length (Fig. 13). Leptospire is a right-handed helix, with 18 or more coils per cell, frequently forming hooks at one or both ends. Hooks at both ends gave rise to the species name *L. biflexa*, and a hook at one end was thought to look like a question mark, leading to the name *L. interrogans*. The hooks are due to a single endoflagellum at each end of the cell. In liquids, viable leptospire is continuously in motion. In semi-solid (0.2% agarose) conditions, leptospire can be observed by darkfield microscopy to remain motionless for periods of time, with occasional corkscrew-like movements. This resting state may in part explain the ability of leptospire to persist in the environment. Most leptospire is able to remain motile for months in distilled water, and their survival can be significantly prolonged by addition of a substrate such as agarose.

Several different leptospiral growth media have been developed. The standard culture medium is Ellinghausen-McCullough-Johnson-Harris (EMJH) medium, which provides long-chain fatty acids in the form of tween (polysorbate) as an energy and carbon source, several divalent cations (Ca^{2+} , Mg^{2+} , Zn^{2+} , and Mn^{2+}), iron, and vitamins (thiamin and cobalamin). EMJH medium contains bovine serum albumin (BSA), which is thought to function by preventing fatty acid oxidation, which is toxic for

spirochetes, and by providing additional trace nutrients. BSA is expensive and batch-to-batch variability in its ability to support leptospiral growth is a major problem. Serum is not required for EMJH but is often added to promote growth. Another problem with BSA-containing media is that due to prion concerns many countries, including the United States, require any bovine products such as BSA to be autoclaved prior to import. A non-BSA containing leptospiral medium that can be used as an alternative transport medium is modified Kortoff medium, which consists of peptone, salts, and 8–10% heat-inactivated slightly hemolyzed rabbit serum. The optimum growth temperature is 30 °C.

Phylogeny

A number of different *Leptospira* species have been described with a range of pathogenic potentials (Fig. 14). On one end of the spectrum are the nonpathogenic saprophytic species, including *L. biflexa* and *L. wolbachii*, which are unable to cause infection. On the other end of the spectrum are the pathogens, including *L. interrogans*, which are able to produce lethal infection in a variety of mammals, including man. Species with intermediate pathogenicity, such as *L. fainei*, can be isolated from clinical specimens, but cause minimal or no disease. Leptospire can also be classified serologically, and over 250 different named serovars have been described. Serovars are classified into one of 28 different serogroups on the basis of antigenic cross-reactivity. Serovar specificity appears to be driven by the carbohydrate structure of lipopolysaccharide side-chains, a dominant antigen on the leptospiral surface.

Fig. 14 Phylogenetic tree of the *Leptospira*. Comparison of leptospiral 16S rRNA sequences shows segregation into three relatedness clusters: Nonpathogens (lower left), pathogens (lower right) and organisms with intermediate pathogenicity (upper section).

There is limited correlation between the genetic and serologic classification systems, with serologically identical strains occurring in multiple species.

The phylogenetic and antigenic diversity of *Leptospira* spp. reflects their ability to adapt to a variety of different environmental niches. Leptospirae have been isolated from most animal species (including reptiles and amphibians) and natural bodies of fresh water wherever the effort has been made. Presumably, leptospirae represent an ancient branch of the bacterial family tree that has coevolved with vertebrates. In reservoir host animals, leptospirae have developed a unique commensalist strategy. Organisms with the capacity to infect animals typically reside in the lumen of the proximal renal tubule and are shed into the environment in the urine. The fluid within the proximal tubule is a nutritionally rich filtrate of serum and is yet an immunologically protected site; kidney sections of infected rats show little or no inflammatory reaction surrounding infected tubules. By not subjecting their host to any detrimental effects, this arrangement effectively affords leptospirae a “free ride” for the life of the animal host. The life-cycle of the organism is completed when organisms released into the environment encounter a new host through adhesion, vascular invasion, and dissemination to the kidney.

Genome sequences provide insight into differences between the various leptospiral lifestyles. The free-living saprophytic nonpathogen, *L. biflexa*, has a genome size of 3.96 Mb, with a relatively high coding density and an abundance of signal transduction genes enabling it to respond to the unpredictable environmental stresses found outside the host. In contrast, *L. interrogans* has a biphasic lifestyle and seems equally at home in the aquatic environment and in the mammalian host. The 63% of *L. interrogans* genes shared with *L. biflexa* consist of essential housekeeping genes and genes important in survival outside the host. The other 37% of *L. interrogans* genes are presumed to be important for life within the mammalian host. On the other end of the spectrum is *L. borgpetersenii*, which has evolved into an obligate parasite of cattle. Infection occurs through direct contact with carrier animals, *L. borgpetersenii* has limited survival outside the host and is difficult to culture. This host dependence is reflected in the erosion of the *L. borgpetersenii* genome; many of its genes are lost or inactivated by mutations or transposon insertions. *L. borgpetersenii* has only about half the signal transduction genes that *L. biflexa* has, confirming the “locked-in” nature of its host dependency.

Pathogenesis

To acquire the ability to invade and colonize the mammalian host, *L. interrogans* has acquired a large array of novel genes. Some of these pathogen-specific genes are known to encode outer membrane proteins such as the porin, OmpL1, and a number of lipoproteins, some of which are involved in host-pathogen interactions. An essential host-pathogen interaction that distinguishes leptospiral pathogens from saprophytes is serum resistance. Leptospiral serum resistance is mediated, at least in part, by LenA, an outer membrane lipoprotein found exclusively in leptospiral pathogens. LenA binds Factor H, a complement regulatory protein that prevents the alternative pathway of complement from damaging host cell membranes. Leptospirae (and other spirochetes) coat their surfaces with Factor H to avoid the bactericidal effects of complement.

Pathogenic leptospirae coat their surfaces with additional host factors using proteins belonging to the Lig (leptospira immunoglobulin-like repeat) family. Leptospiral pathogens, but not the saprophytes, have between 1 and 3 Lig proteins. Ligs are very large (112–220 kD) proteins containing a series of 12–13 immunoglobulin-like repeats, some of which mediate high-affinity binding to multiple host proteins, including fibronectin and fibrinogen. Interactions with host proteins are facilitated by induction of Lig expression in response to levels of osmolarity (300 mOsm) found in host tissues. Lig expression by leptospirae grown in EMJH, which has low osmolarity (67 mOsm), is poor. Addition of salt (or any other osmotically active molecule) to EMJH medium rapidly induces Lig expression. As a second regulatory mechanism, Lig expression is posttranscriptionally regulated by temperature. Temperature-sensitive RNA stem-loop structures sequester the *lig* ribosome binding site and start codon preventing translation. In these ways, leptospirae in low osmolarity, low temperature aquatic environments are saved the metabolic expense of expressing Lig proteins until they are needed for colonization of a warm-blooded host.

Acquisition of virulence genes was essential in the evolution of leptospirae from free-living to pathogenic organisms. Genes appear to have been horizontally transferred from a variety of sources. For example, the gene encoding the major outer membrane lipoprotein, LipL32, is highly conserved among leptospiral pathogens, does not occur in the nonpathogens, and appears to have been acquired by a gene insertion event. LipL32 has recently been shown to be primarily subsurface, exposed on the periplasmic side of the outer membrane. The function of LipL32 is unknown and does not appear to be required for virulence; an *L. interrogans* *lipL32* mutant was found to retain the ability to cause acute infection in hamsters and chronic infection in rats. Horizontal genetic transfer also occurs between leptospiral pathogens; 20% of *ompL1* genes are mosaics containing fragments of multiple leptospiral lineages. However, permissiveness for gene acquisition is a double-edged sword—the genomes of leptospiral pathogens have much higher numbers of insertion sequence (IS) elements than the nonpathogens. The IS elements contain transposon genes that, once they infect the genome, mediate IS element proliferation and gene disruption. IS elements appear to be a major mechanism of genome erosion in *L. borgpetersenii*. Transposons are now being put to good use in leptospiral research—leptospiral pathogens had been much more difficult to transform than the nonpathogens, which had been a major impediment in leptospiral pathogenesis research. Now, however, the mariner transposon has been found to be useful for manipulating the genome of leptospiral pathogens—hundreds of single-gene knock out mutations have been generated in *L. interrogans*. Mutants with disrupted LPS, outer membrane protein, regulatory, and motility genes have been found to have reduced virulence for hamsters, providing new insights into leptospiral virulence.

Epidemiology and Disease

Leptospirosis epidemiology has traditionally been carried out by serotyping isolates or examining the serologic response of infected patients. However, serologic approaches are fraught with problems, including the frequent observation that patients' antibody responses may not be specific for the infecting serovar. Genetic tools provide more accurate molecular approaches for tracking the epidemiology of leptospirosis. Genome sequencing technology is replacing 16S sequencing, DNA-DNA hybridization, and multi-locus sequence typing for leptospiral species and strain identification. Approaches such as these reveal that rat-associated strains of *L. interrogans* are frequently the cause of leptospirosis outbreaks in urban settings. Rats are found wherever people live and wherever the studies have been done, urban rats are found to have a high leptospirosis carriage rate in their kidneys. The prevalence of leptospiral carriage among the ubiquitous *Rattus norvegicus* is probably the reason that leptospirosis is the most widespread zoonosis. Leptospirosis occurs less frequently in westernized countries because housing standards are effective at excluding rats from human living spaces. However, in developing countries with poor housing standards, leptospirosis outbreaks occur regularly in urban settings after heavy rainfall and flooding.

Leptospirosis infections range in severity from self-limited flu-like illness to multiorgan system failure and death. After an incubation period of 5–14 days, there is the onset of fever, myalgia, headache, abdominal pain, nausea, and vomiting. In tropical regions where leptospirosis typically occurs, these early nonspecific symptoms can be confused with dengue fever or malaria. When observed, conjunctival suffusion (scleral redness without discharge) can be a distinguishing sign of leptospirosis. During this initial septicemic phase, spirochetes can be recovered from the blood and spinal fluid. Formation of agglutinating antibody leads to clearance of organisms and, in milder cases, a temporary resolution of symptoms. However, a second, immune phase of the disease may follow, with milder fever, headache, and vomiting. In more severe infections, the initial phase progresses rapidly to jaundice and renal failure, known as Weil's syndrome, with a mortality rate of 10%. The renal failure due to leptospirosis is a unique form of kidney dysfunction associated with high urine output and low serum potassium levels. At this stage, complications can be avoided with replacement of fluids and electrolytes. If, on the other hand, dehydration occurs and renal failure ensues, access to peritoneal or hemodialysis is essential for survival. Certain strains of *L. interrogans* cause acute lung involvement with shortness of breath due to airspace hemorrhage and a much higher mortality rate of 50%.

Pathogenic leptospires are highly susceptible to common antibiotics including doxycycline and ampicillin and it is likely that antibiotic therapy given at the first signs of infection would significantly reduce morbidity and mortality. However, currently available diagnostic tests have relatively low sensitivity during early infection and patient populations at highest risk typically have poor access to medical care. Recent studies show that most patients with early infection have antibodies to the Lig proteins. What is needed is a diagnostic test that is portable, easy to use, does not require electricity, and has a long shelf-life at room temperature. Whole-cell vaccines are used widely in domestic animals, including dogs, pigs, and cattle. A similar vaccine has been found to be effective in humans, but is generally not available because of concerns regarding side-effects and a relatively short duration of immunity. A preventative approach for adventure travelers participating in water sports in areas with a history of leptospirosis is weekly doxycycline, which has been shown to be effective in US soldiers undergoing jungle training in Panama. Doxycycline is not appropriate for children or pregnant women and may cause photosensitivity or gastrointestinal side-effects. An alternative approach recommended by some travel-experts is weekly azithromycin, which has a better safety profile, but has not been rigorously tested for efficacy.

Conclusions

Spirochetes are widely distributed in nature as free-living bacteria, as metabolic symbionts of insects, and as commensals and parasites of animals. *Spirochaeta* spp. isolated from natural bodies of water are related by 16S rRNA sequence analysis to treponemes found in the oral cavity and in the digestive tracts of termites. *Borrelia* spp. also have the ability to colonize the digestive tracts of insects, in this case ticks and lice, which serve as vectors for transmission to animal host reservoirs. *Brachyspira* spp. colonize digestive tracts of animals either as commensals or parasites. *Leptospira* spp. exist as free-living organisms or cycle between the aquatic environment and animal host reservoirs via their renal tubules. The diversity of spirochete life-styles demonstrates the functional versatility of their unique morphology and mechanism of motility.

Spontaneous Generation

J Strick, Franklin and Marshall College, Lancaster, PA, USA

© 2009 Elsevier Inc. All rights reserved.

Glossary

abiogenesis Term used in 1870 by Huxley to mean life arising from a combination of inorganic starting materials. Since that time, has come to be used more widely to indicate origin of life from any nonliving matter.

archebiosis Term coined by Bastian in 1870 to mean life arising from strictly inorganic starting materials.

biogenesis Term used in 1870 by Huxley to mean life arising only from other living things, the opposite of which he termed abiogenesis. The term seems to have been first coined by Bastian earlier that year, but to mean exactly the opposite: spontaneous generation. It is Huxley's usage that became famous and remains the definition of this term today.

heterogenesis Nineteenth century term used to mean the origin of living things from organic materials, for example, from infusions of plant or animal matter, or from decaying tissue in a diseased or dying organism. Thought to be the source of tumors, parasitic worms, microorganisms from putrefaction, as these organized themselves from the smallest microscopically visible particles (molecules) of organic tissues. Note that many supporters of heterogenesis might not support the more extreme position of archebiosis/abiogenesis from inorganic matter.

molecules Term used from the writings of Buffon (c.1750) onward to indicate the tiniest (bacteria-sized) microscopically visible particles of organic matter in blood, tissue, infusions, and so on. This term was used by histologists, pathologists, and cytologists until the 1870s, obviously in a way quite different from the chemists' use of the term that developed through the same time period. Important examples include the 'active molecules' of Robert Brown (1828–29), the cellforming cytoblastema 'molecules' of Theodor Schwann (1839), and the histological 'molecules' of John Hughes Bennett (1840–75). Many thought clumping together of these units was the basis for heterogenesis.

pleomorphism The doctrine that microorganisms did not come in distinct, stable Linnean species but rather were highly variable in shape and metabolic capabilities in response to changes in their environment. Many believed this to be true of the bacteria, especially in Britain and Germany through the 1880s. More extreme versions held that bacteria, yeasts, molds, and algae were all interconvertible stages in the life cycle of a single organism. Heterogenesis can be seen as the next logical step, including the transition from nonliving organic matter to the simplest bacterial forms as but one more stage in that fluid transformability.

Introduction

The idea that living things can originate from nonliving materials, spontaneous generation, has a long history, inseparably intertwined until about 1880 with the development of microbiology as a science. No less an authority than Aristotle claimed that cases of spontaneous generation could be observed in nature, and his support was important in establishing the idea for many centuries. Beginning around the time of the Scientific Revolution of the seventeenth century, however, the doctrine of spontaneous generation was increasingly challenged and became the subject of numerous episodes of controversy. As combatants tried to answer one another's criticisms, the new breakthroughs in technique and in experimental design that were developed served as some of the most important foundations upon which a science of microbiology could be built. As just one example, the development of a sterile technique as well as procedures to sterilize glassware and growth media all grew directly out of experiments trying to prove or disprove the possibility of spontaneous generation of microorganisms.

In seeking to answer a question as basic as how life originates, theory played a role as important or more so than technique or experiment. From the first, the doctrine of spontaneous generation was seen to be fraught with religious implications. If life could originate spontaneously from lifeless matter, the position of philosophical materialism, then a Creator God was irrelevant. If spontaneous generation occurred in present times, this was at odds with a single original Creation as told in the Bible. However, for those interested in a naturalistic worldview, such as supporters of Darwinian evolution, there was also a potential conflict. The doctrine of evolution was based on a profound philosophical assumption of continuity in nature, that is, that there were no sudden unbridgeable gaps between similar living forms, which would require supernatural intervention. Furthermore, Darwin's theory implied that the vast diversity of living things had come from one or at most a few original ancestral organisms, and these must have originated somehow. For many, then, to believe in evolution and a completely naturalistic worldview required the belief that no unbridgeable gap occurred between living matter and nonliving matter and that living organisms must have been capable of arising from nonlife, at least once on the early earth. Those with this view, for example, Henry Charlton Bastian,

This article is a reprint of J. Strick, Spontaneous Generation, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 80–90.

challenged hypocrisy on the part of those who supported Darwin but were unwilling to believe in the necessity of spontaneous generation.

Still another important source of disagreement, even among scientists who claimed not to care about religious implications, was fundamental epistemological assumptions about the nature of life. Some believed very deeply that all living things must reproduce by 'seeds' or 'germs', by analogy with the large number of organisms for which this process had been observed. So fundamental was this belief that, even in cases where microscopic life appeared in tubes of fluid boiled for hours, those scientists concluded that either the tubes must have leaked after boiling or there must be some kind of structures produced by microorganisms that were capable of withstanding previously unheard of temperatures, even though nobody had ever seen such structures. Their opponents, as late as the 1870s, believed that the most clearly observed and reliably established fact known about living things was that they were totally unable to survive the boiling temperature of water for more than a few minutes. From this equally tenable premise, they concluded that spontaneous generation was a less strained explanation of organisms in boiled infusions than the *ad hoc* invoking of 'spores' that nobody had ever experimentally demonstrated with totally unprecedented heat-resisting abilities. Thus, before ever carrying out an experiment, both sides in the spontaneous generation controversies were often begging the question at issue. Clearly, these philosophical issues were crucial points showing how experimenters could disagree because they were talking past one another, more than because of differences in the experiments themselves. The doctrine of spontaneous generation rose and fell in popularity repeatedly at different times in different countries in the past several centuries, and to tell the story of spontaneous generation controversies only as a series of battles about 'dueling experiments' would be to misunderstand much or even most of what the controversies were really about.

Early History

From antiquity it had been maintained that frogs, eels, mice, and numerous worms and insects, especially parasitic worms living inside animals, could arise by spontaneous generation, mostly heterogenesis. With Leeuwenhoek's discovery of microorganisms, many naturalists assumed that these too could arise without parents. Indeed, as microbes seemed exceedingly simple, and bacteria simplest of all, it was believed that they were the most likely to be organizable from nonliving materials. Francesco Redi, natural philosopher to the same Tuscan court that was patron to Galileo, carried out some famous experiments in 1668 that investigated specifically the origin of insects. Redi's experiments showing that maggots come from fly eggs, not from rotting meat, usually led off histories of spontaneous generation debates. It was commonly believed until that time that the appearance of maggots in rotting meat was a clear example of spontaneous generation. Redi placed samples of many different types of meat and fish in glass jars. One set of jars was open to the air and soon swarmed with maggots. The other set was covered with fine muslin cloth. Redi saw that, while maggots never appeared in the meat of those jars, flies crawled about on the cloth and sometimes laid eggs there. Those eggs were seen to hatch into maggots, disproving spontaneous generation as their origin. Though Redi himself continued to believe that some insects, such as gall flies, did arise by spontaneous generation, many naturalists assumed from this time onward that spontaneous generation, if it occurred, only did so among parasitic worms and microorganisms.

Of course, working at the time of the Scientific Revolution, Redi did participate at a time when experiment came to the fore as an activity ever afterward central in natural philosophy. Spontaneous generation debates, like all other natural philosophic questions, featured experiments more and more prominently from the late seventeenth century onward. Just as 'natural history' or 'natural philosophy' historically did not mean what is now called 'science' until fairly recently, neither did 'experiment' always mean what it means now. Many natural philosophers in the seventeenth century were interested in the power of the experimental method, but were just as interested in public demonstrations of 'experiments' as a way of convincing audiences, for example, prospective patrons, that their enterprise was qualitatively different from the book-dominated natural philosophy of the past, and from the subjective and often bloody religious disputes that had traumatized European life for over a century. Recent studies have looked closely at Redi's career, especially his relationship with the Medici Grand Dukes, his principal patrons. One such study concludes that Redi's public demonstration of experiments was a form of court entertainment in which the final arbiter of the meaning and success of the outcome was the Grand Duke. Thus there was a world of difference between Redi's procedures and what would be the nineteenth century be called 'controlled experimentation by a biologist'. He set high value on repeated observation and demonstration, saying, "I do not put much faith in matters not made clear to me by experiment." Paradoxically, however, he suggested elsewhere that he experimented "in order to make myself more certain of that of which I am already most certain." For Redi, then, especially in his primary role as an early modern courtier, 'experiment' meant something quite different from what we understand by that term today, particularly with regard to the role of 'preconceived expectations'. The paradox results only if we assume in a naively ahistorical way that what Redi called 'experiment' should be assumed to have the same meaning that term came to have after 'natural philosophy' had been transformed into 'science'.

Once we gain this richer sense of what experiment meant in the historical context in which Redi lived and worked, we may begin to question the validity of an ahistorical narrative that uncritically compares his work with experiments performed by Pasteur, Tyndall, and their antagonists two centuries later, merely because of superficial similarity in 'the use of controls'. Perhaps there are more similarities in the meaning of 'experiment' in such different historical settings, but this is an open question that can only be answered by looking at the full context in which each investigator had to operate, including such questions as the existing system of patronage upon which each depended to support work on scientific pursuits. Such points of comparison will be developed further when discussing Pasteur's work.

The Needham/Spallanzani Controversy

Eighty years after Redi, in 1748, another series of experiments by the Irish priest John Turberville Needham was published, and this time was widely believed to support the spontaneous generation of microorganisms. Needham soon collaborated with the French aristocrat Comte de Buffon. And over the next several decades the work of Buffon and Needham was opposed by many, including Charles Bonnet and Lazzaro Spallanzani.

Needham's first experiments found that, when mutton gravy was stoppered and sealed with mastic in glass tubes and heated to boiling for a time, the fluid afterward teemed with microorganisms (protists). Buffon and Needham later reported seeing tiny particles (in the size range of bacteria) that they called 'organic molecules', which came from disintegrating organic material and moved very actively. These, they said, clumped together to form the larger animalcules (protists). They also claimed that sealing and boiling proved that the molecules did not originate from "insects or eggs floating in the atmosphere." Most naturalists considered this, if true, to be a case of spontaneous generation.

Spallanzani, an Italian cleric, carried out experiments challenging these claims and first published his results in 1765. His opposition was based on two main arguments. First, he said that with his own microscope he never saw anything like the 'organic molecules' and therefore charged that Buffon and Needham were only seeing what they wanted to see, because Buffon's philosophy of nature had predicted that such particles must exist. This claim was widely repeated. Second, he said that when he boiled infusions similar to Needham's, he did not find any living microbes in them, as long as he sealed the tubes by melting the glass shut in a flame before boiling and continued the boiling for at least an hour. Thus, Spallanzani claimed that the microorganisms in Needham's infusions must indeed have gotten in, despite Needham's precautions, from the atmosphere after boiling.

Needham responded that boiling for as much as an hour would clearly be so severe a treatment as to deprive the air in the tubes of its power to generate or support life. Later experiments showing that indeed such treatment decreased or consumed the oxygen content in the tubes seemed to support Needham's claim. Thus the experimental outcome was underdetermined by the experiments themselves, so the controversy was able to continue through the 1780s.

A popular notion of experiment has it that 'proper science' can only occur when the scientist approaches his experiment with no 'preconceived ideas' about the outcome, and intends to "let the chips fall where they may." In many histories of the spontaneous generation debates, the 'losers' are often accused of having been biased beforehand by their belief in a 'vital force' or some similar overarching philosophy, while Redi, Spallanzani, Pasteur, and Tyndall epitomize the openminded investigator. A closely related claim has been that Spallanzani, Pasteur, and others were often able to defeat their foes by virtue of possessing better instruments, especially superior-quality microscopes. Thus, as the story has been told since the early nineteenth century, the Comte de Buffon and his collaborator Needham in the 1740s were portrayed as 'armchair philosophers' who cooked up a doctrine of 'organic molecules', a vital 'plastic force', and spontaneous generation; and they had such an inferior microscope that they were able to interpret whatever fuzzy images they saw as supporting the fuzzy ideas they wanted the data to confirm. Victorian biologist T. H. Huxley's version established one of his most famous clichés by describing Buffon and Needham's work as an object lesson for generations of young scientists:

Such as it was, I think it [Buffon and Needham's doctrine] will appear ... to be a most ingenious and suggestive speculation. But the great tragedy of Science – the slaying of a beautiful hypothesis by an ugly fact – which is so constantly being enacted under the eyes of philosophers, was played almost immediately, for the benefit of Buffon and Needham.

Huxley (1870) *Biogenesis and Abiogenesis*. In: *Discourses Biological and Geological, Essays*, New York: Appleton, 1925, pp. 232–274, 239

Huxley argued, based perhaps on Pasteur's similar claim, that Buffon and Needham had a poor microscope and their opponent Spallanzani had a much more objective outlook and understanding of the method of controlled experiment.

Though seldom emphasized, it is very important to note that spontaneous generation was seen to be directly supportive of two other broader doctrines: epigenesis and materialism. Epigenesis is the doctrine that all the parts of an embryo are assembled gradually, having at first been nonexistent. Epigenesis was opposed in the seventeenth and eighteenth centuries by the doctrine of preformation, which claimed that all embryonic organs existed inside the sperm or the egg in miniature from even before fertilization and only needed to grow, unfold, and expand as gestation proceeded. This implied logically that all the generations of, for example, humanity must have been contained, each within the previous one like Russian dolls, all the way back to the eggs in Eve's ovaries or the sperm of Adam. (The overwhelming majority of naturalists writing during this period were Christian.) Since Buffon and Needham's description of the origin of protist microbes suggested their organization from originally homogeneous 'molecules', this seemed a blow for preformationists. Buffon indeed ridiculed preformation theory, insisting that the microscope showed no trace of these successively enclosed generations within the sperm or eggs of animals. Spallanzani eventually came down on the side of preformation and rejected Needham's theory. We would probably admit today that, since his microscope could not have shown him little preformed homunculi inside eggs or sperm cells, Spallanzani, too, must have been willing to go some way in believing in things he could not verify and was thus also operating in an atmosphere of 'philosophizing'.

More than that, if Buffon and Needham's observations were correct, they showed that matter contained within itself all the properties necessary to organize into life. This was the basic tenet of philosophical materialism, a doctrine profoundly at odds with Christianity or any kind of Deism. Voltaire, among others, feared that Needham's claims would support atheism and materialism. It was thought by many that this theory implied that life could originate by a chance, random combination of substances. This was

so contrary to mainstream religious beliefs, and to a natural philosophy still very much in the service of demonstrating the existence of a beneficent Creator, that it generated heated opposition. Further, this led to spontaneous generation becoming strongly associated, beginning around 1750–70, with atheism, materialism, and political radicalism. (Since this chance combination of chemicals has become such a crucial element of modern views of the origin of life, such as the famous 1953 Urey–Miller experiment, it is interesting that Buffon and Needham are not celebrated as thinkers far ahead of the religious biases of their time. Voltaire seems to have been one of those who most actively spread the opinion that Needham and Buffon were poor scientists, though this was based on seriously misreading Needham.)

Only recently for the first time has close study been applied to the actual technical evidence on what kind of microscopes were being used by Spallanzani and by Needham. This work has shown that Buffon and Needham's results cannot be successfully explained by assuming that they worked with poor instruments, nor that their work was sloppy or biased in advance by *a priori* theorizing, despite the fact that these explanations are ubiquitous among previous accounts of the controversy. Indeed, a close review of the evidence on the actual experiments suggests that the experiments of Needham and Buffon were careful, high-quality work with quite a bit of sophisticated hypothesis formation and testing.

Many of the contemporary critics of Buffon and Needham, including Spallanzani in the 1760s, had originated this claim of *a priori* bias, at least partly because they assumed the pair to have worked with a British Cuff compound microscope, common at that time (Figure 1). This type of device had a maximum magnification of only about 100 $\times$, and even at that low power the image it produced suffered from severe chromatic and spherical aberration, as indeed was a problem with all compound microscopes prior to the achromatic lenses not perfected until 60 years later. By careful analysis of the original publications, however, it has been shown that the instrument used by Needham was actually a high-quality single lens microscope of the Wilson screw-barrel design, capable of at least 400 $\times$ magnification with outstanding resolution, that is, not plagued by the aberrations of compound scopes (Figure 2). This was similar to the instrument with which Robert Brown discovered the cell nucleus in plant cells and Brownian movement in pollen particles in the 1820s and 1830s. In fact, Buffon and Needham's observations anticipate those that led to the discovery of Brownian movement, their 'organic molecules' being what Brown called 'active molecules'. The simple microscope employed in the famous experiments by Spallanzani was a variant of the Lyonnet aquatic microscope. Spallanzani's instrument was

Figure 1 Plate from Buffon's *Histoire naturelle* depicting an eighteenth century scientist using the compound Cuff microscope. Perhaps because of the illustration, many assumed that Buffon and Needham had used this instrument to make their observations, when in fact they had used the much superior Wilson screw-barrel design (see Figure 2). Compound microscopes of that era suffered from severe chromatic and spherical aberration, and the Cuff microscope had a maximum magnification of only about 100. Courtesy of Beinecke Rare Book and Manuscripts Library, Yale University.

Figure 2 Single-lens Wilson screw-barrel microscope used by Buffon to make his observations in support of his interpretation of the theory of spontaneous generation. In this theory, smallbacterium-sized particles, which Buffon called ‘organic molecules’, clumped together to form living ‘animalcules’. Courtesy of Beinecke Rare Book and Manuscripts Library, Yale University.

incapable of the short focal length, high-resolution work permitted by the Wilson screw-barrel design, so that he could not even see the bacteria-sized ‘organic molecules’ under dispute. Thus the truth of this controversy appears to be that Spallanzani was the technically handicapped participant, though exactly the opposite story has become universal. Buffon and Needham’s discovery of ‘organic molecules’ was not the work of imagination but an actual discovery of active molecules and of Brownian movement, some 80 years before Brown. This explains why Buffon and Needham refused to back down from their original observations despite accusations of atheism and decades of controversy. Furthermore, both parties seem to have had plenty of *a priori* philosophical commitments at stake, and nobody approached as explosive a subject as materialism with a completely open mind.

Worms, Molecules, and Evolution

The appearance of parasitic worms within animals was long seen, until perhaps the 1840s, as the strongest single piece of evidence supporting spontaneous generation claims. The complex life cycles of most of these parasites involved intermediate life cycle stages that had to live in other host animals. Thus, egg-feeding experiments would not have been able to show eggs from one animal directly producing worms in another. Only in the 1840s and 1850s, with the working out of the complex life cycles and intermediate hosts, did it finally become unambiguously clear that the worms reproduced via eggs.

Despite the denunciation of Buffon and Needham, a great many pathologists, histologists, and, later, cytologists continued to observe bacteria-sized, actively moving particles in blood, tissues, and infusions. These particles continued to be called ‘molecules’ by life scientists. They were using the term, obviously, in a way quite different from the chemists’ use of the term that developed through the same time period. Important examples include the ‘active molecules’ of Robert Brown (1828–29), the cellforming cytoblastema ‘molecules’ of Theodor Schwann (1839), and the histological ‘molecules’ of John Hughes Bennett (1840–75). Many thought clumping together of these units was the basis for heterogenesis, and that this furthermore supported epigenesis as the correct explanation of embryonic development. Especially vocal in this belief were Lorenz Oken, Karl Burdach, and other German

biologists of the *Naturphilosophie* school. (It should be emphasized that neither Brown nor Schwann themselves interpreted their ‘molecules’ in this way, and Schwann did some significant experiments early in his career that seemed to disprove certain cases of spontaneous generation.) In Britain, both Charles Darwin and Richard Owen worked in private on the molecule theory during the 1830s, as did William Addison in the 1840s. More importantly, the British histologist Hughes Bennett was one of the first professors to teach a physiology course in a university and medical school, and he taught from 1840 until almost 1870. His theory of ‘molecules’ as the essential units from which cells formed, explicitly embracing heterogenesis by the late 1860s, was thus widely influential among British scientific and medical circles for over a generation.

J. B. Lamarck, the early French evolutionist, had made spontaneous generation of microorganisms an integral part of his evolution theory from its beginning in 1800. Lamarckian supporters were numerous and widespread, though often associated with radical politics, as selforganization and development of matter was seen as a crucial scientific underpinning for democratic, bottom-up organizing political theories. A few such Lamarckians did rise to university teaching posts, however, and notable among them was the outspoken British comparative anatomy professor Robert Grant. Though considered not quite respectable in Victorian intellectual circles, his teaching of evolution and spontaneous generation continued from the 1820s through his death in 1874, and thus gave those ideas a presence in British thought decades before *On the Origin of Species* appeared. Charles Darwin, for instance, was one of Grant’s earliest students and protégé’s (though Darwin later felt he had to avoid any contact with the less-than-respectable Grant when he was developing his own evolution theory in secret for 20 years). Grant and other Lamarckians had established in the public mind a strong link between evolutionary theories and spontaneous generation.

The Role of Louis Pasteur

As Louis Pasteur’s experiments on spontaneous generation, particularly his ‘swan-necked flasks’, are among the most famous of all, the Pasteur–Pouchet debate of the 1860s in France deserves close attention. It is also worth noting that the Historical Introduction to Pasteur’s famous 1862 Memoir on the subject has served as the model upon which almost all subsequent histories of the controversy were based for over a 100 years. This has led to the casting of the controversy as a series of what I call ‘dueling experiments’, and has often stripped it of its crucial philosophical context. Pasteur also chose to leave out an entire chapter of the story: the argument that parasitic worms must have arisen by spontaneous generation. So dominant has Pasteur’s master narrative been that it is only with historical detective work in the early 1970s that this omission of Pasteur’s was finally restored to its place of importance in the story.

Between 1860 and 1862 Pasteur carried out a lengthy series of experiments focusing exclusively on the development of microbes in previously boiled infusions, in response to the experiments in favor of heterogenesis published by Felix Pouchet. With great ingenuity, Pasteur designed numerous experiments that would allow the boiled infusions to come in contact with air that itself had not been altered by the heat, to answer Needham’s objection of a century before. Air was led through dense gun cotton filters, for example, before coming in contact with the infusions. The filters were then dissolved and the solid particles trapped from the air were examined microscopically. Pasteur saw some spherical bodies that he assumed were the ‘germs’ of microbes, since in those infusions microbial life rarely developed. Perhaps most famous of Pasteur’s experiments was a series of flasks which, after being filled with infusion, had their necks heated in a flame then drawn out into long, curved shapes, for example, like a ‘swan-neck’ (Figure 3). Air could enter through the long neck, but dust particles settled in the dip and could not come in contact with the flask’s contents. Again, if these flasks were boiled then cooled, rarely did any microbial growth ever appear in them. However, if the neck was broken off and dust allowed to enter the flask, microbial growth in the infusion soon followed. Pasteur concluded that this proved microbes or their germs were carried on dust particles, so the exclusion of dust followed by no growth meant the disproof of spontaneous generation.

As the swan-necked flasks have in our time become textbook icons for exemplary experimental practice, it is difficult for us to reconstruct the historical period when, even after Pasteur’s famous public lectures on his experiments, a significant number of scientists remained unconvinced. In particular Pasteur claimed to have sweepingly proven that germs must be the source of growth in previously boiled infusions, but his opponents pointed out that what he had shown could be read to be only that dust was a necessary ingredient for spontaneous generation with the yeast/sugar water infusions that he used. Recent historians have also pointed out, as did Pouchet and other supporters of spontaneous generation at the time, that Pasteur never replicated some of Pouchet’s most convincing experiments: those involving boiled hay infusions. (It was only recognized a decade later that the hay bacillus, *Bacillus subtilis*, produces heatresistant endospores.) If Pasteur had tried his famous swan-necked flask method with a hay infusion, it has been suggested that the debate might have ended quite differently on this point alone.

Since even in this most famous of textbook cases, it still seems the experimental evidence at the time was not as finally conclusive as Pasteur declared it to be, why did the French Academy of Sciences award the victory to Pasteur and declare the spontaneous generation controversy settled once and for all? Spontaneous generation was still just as politically and religiously charged a subject in the French Second Empire of Louis Napoleon as it had been 100 years earlier in Buffon and Needham’s time. Furthermore, while spontaneous generation had in the past tended to be associated with the doctrine of transmutation of species, the latter doctrine was currently undergoing a particularly heated wave of notoriety in the wake of the recent publication of Darwin’s *On the Origin of Species*. The first French translation, by Clémentine Royer, of the *Origin* had just appeared in 1862 and was prefaced by a long diatribe by Royer against the Catholic Church. The Church was, however, on closer terms than ever with the conservative government, since Louis Napoleon’s coup of 1851. In this environment, since the Academy of Sciences was a state-supported institution, Darwinian

Figure 3 Pasteur's illustrations of his 'swan-necked flasks'. Courtesy of the American Society for Microbiology Press.

evolution was regarded in France as a politico-theological doctrine allied with forces that threatened the Church and State. In addition, spontaneous generation was seen as directly undermining belief in a providential Creator, so that the outcome of the Pasteur–Pouchet debate carried implications of enormous importance to the power structure of the Second Empire. Even foreign savants observing the controversy at the time, including Britain's premier anatomist Richard Owen and Germany's Friedrich Lange, noted that opposition to spontaneous generation seemed intimately tied to support for the forces of conservatism and the established Church.

The force of Pasteur's experimental genius has been surpassed historically only by his rhetorical skill. For, while he broached all these controversial subjects in a famous 1864 Sorbonne lecture on spontaneous generation, yet he succeeded in portraying himself (and science done at its best) as able to remain entirely aloof from such matters, saying that he had approached the question in a totally unbiased manner, equally ready to accept or reject the existence of spontaneous generation, based solely on the outcome of the experiments. While Pasteur was truly an experimental genius compared to Pouchet, the crucial problem with this "let the chips fall where they may" portrayal of himself is that it is not true. By this time Pasteur had been dominated for some years already by his own preconceived notions (derived from his work on crystalline asymmetry) of life as dependent upon a Cosmic Asymmetric Force. He had done numerous experiments in private, trying to produce living conditions in the laboratory by application of light, electricity, and magnetism to experimental setups, and he was convinced that Pouchet was wrong, not so much because spontaneous generation was somehow impossible, but because Pouchet was not aware of the importance of asymmetric forces to the problem of life, and was not approaching the experiments by that route. Furthermore, Pasteur was fully aware that all of his important scientific patrons were entrenched in the conservative regime, and he was constantly trying to cultivate those contacts, particularly with the Emperor and Empress personally. Thus it is no surprise that during all the years of the Second Empire he kept silent about his own attempts to simulate or create life in the laboratory and concentrated in public on refuting the work of Pouchet, which he knew to be very unpalatable to the Academy and the State.

The British Debate of the 1870s: Darwin, Spontaneous Generation, and the Germ Theory of Disease

Charles Darwin himself had remarkably ambivalent feelings about spontaneous generation. In the first edition of *On the Origin of Species* he appears to have carefully avoided the topic through almost the entire book. Then in a single throwaway line near the very end, he upset many of his supporters by adopting this language:

Therefore I should infer from analogy that probably all the organic beings which have ever lived on this earth have descended from some one primordial form, *into which life was first breathed.*

Darwin, *On the Origin of Species*, London: John Murray, 1859, p. 484, italics mine

In the second edition, released just 7 weeks later on 31 December 1859, Darwin made it "... breathed by the Creator." Darwin received much criticism, from both supporters and opponents of evolution, about dissembling in this passage. In the 1862 third edition he simply dropped the entire phrase after "one primordial form" and left it that way through all remaining editions of the *Origin* in his lifetime, essentially taking a public position of 'no comment' on the implications of his theory for the origin of life on Earth. In private, to close confidantes, he said, "I have long regretted that I truckled to public opinion, and used the Pentateuchal term of creation, by which I really meant 'appeared' by some wholly unknown process. It is mere rubbish, thinking at present of the origin of life; one might as well think of the origin of matter." He thought Pasteur's experiments much more convincing than Pouchet's. But to others Darwin said it would be a great thing if spontaneous generation could be proven, as it would undergird his theory in an important way. His reluctance to discuss the matter in 1859 seems to have become genuine ambivalence on the topic.

On the British scientific scene in the 1860s and 1870s the most entrenched advocates of spontaneous generation and those most resistant to the germ theory of disease were the medical community. At that time, despite Pasteur's suggestive research on silkworm diseases, British doctors strongly favored a theory of contagious disease as analogous to fermentation via chemical catalysis, a theory first promulgated by Justus Liebig in the early 1840s. This was in part due to a brief but highly publicized theory of 1849 that cholera was caused by a fungus. When the supposed cholera fungus was soon discovered to be a common mold contaminant, many British medical men who might have had leanings toward a germ theory felt that it had been discredited. Thus, when Pasteur's claims of the mid-1860s reached Britain, most British doctors were skeptical that living microbes were the sources of contagion, and they continued to favor a chemical poison, viewing the microbes as some kind of product or concomitant of the disease process rather than its cause. Thus, when the physicist John Tyndall gave a famous lecture on "Dust and Disease" in January 1870, arguing that doctors must accept the germ theory of Pasteur in order to have any really scientific approach to disease, many British doctors took offence. Tyndall was known for his brash public persona and as a general spokesman for science in London society circles. In addition to his quite haughty tone, he was trained as a physicist and certainly had no clinical experience of disease or of the role of patients' constitutions in causing their susceptibility to be so highly varied. So it was not surprising that doctors accused Tyndall of being an interloper in biology and medicine, an area where his opinions had no weight. They thought he was totally unaware of the cholera fungus hoax of 1849 and of other important technical reasons for medical skepticism about an oversimplified germ theory. Tyndall's version of the germ theory denied any role to the 'constitution': it compared patients to so many identical tubes of infusion. If germladen dust particles fell into the patient, he would get sick, Tyndall said. Those in hospitals or towns with epidemics who did not get sick were those who such particles, or 'germ clouds', passed by.

Chief among the medical professionals who opposed Tyndall was Henry Charlton Bastian, professor of pathological anatomy at London's University College Medical School. Bastian was an avowed supporter of Darwin's and Spencer's writings on evolution, and did much experimental work to try to show that microorganisms could arise by spontaneous generation, or biogenesis as he at first called it. Bastian, like Alfred Russel Wallace and many others interested in natural selection, thought at that time that Darwin's theory required spontaneous generation to explain in a nonmiraculous way where the original common ancestor of all species came from. Wallace wrote excitedly to Darwin and in a review in *Nature* in August 1872 claimed that Bastian's findings could help Darwinian evolution out of the time crunch presented by William Thomson's (later Lord Kelvin) challenge: that the age of the earth – a few tens of millions of years at most, by his physics calculations – was utterly inadequate to allow the hundreds of millions of years of evolution. Darwin's gradualist theory required to get from single-celled creatures to complex vertebrates by a single, unbroken chain of descent. Darwin was tempted but still ambivalent. By this time he wrote to T. H. Huxley and J. D. Hooker that he certainly believed that life at first emerged from nonlife by natural processes in 'some warm little pond'. However, Bastian's idea of spontaneous generation going on all the time, everywhere, up to the present meant many different possible lines of descent with new ones beginning constantly, a model similar to Lamarck's. Darwin was still deeply committed intellectually to a single branching tree of descent, which would require only one (or a small handful) progenitor(s) created by an original emergence of life entirely confined to the very earliest period of life on Earth. He followed closely the debates over Bastian's experiments, as did all Darwinians who had come to know Bastian as one of their own, indeed one of their brightest rising young stars in experimental science.

Bastian also thought that bacteria in diseased patients resulted from spontaneous generation, as by-products of the disease process. Between 1870 and 1875 he had published the results of hundreds of experiments in which he showed that bacteria could be found in tubes of various infusions boiled for periods varying from a few minutes up to an hour. Attempting to refute Bastian's work from 1875 to 1877, Tyndall devised an ingenious dust-free cabinet in which to carry out the experiments (Figure 4).

Tyndall's close friend T. H. Huxley was at first interested in Bastian's experiments, but soon concluded that the pathologist must be mistaken in his conclusions, especially given Huxley's belief at this time in pleomorphism. He declared that Bastian "had gotten out of his tubes exactly what he put into them," that is, organisms must have gotten into the tubes as contaminants. Both Huxley and Tyndall were also evolutionists, but found it much easier to believe in living things able to survive boiling somehow (or, even more believable, that Bastian was a sloppy experimenter) than to believe that organisms as complex as protozoa could come from anything other than the 'seeds' or 'germs' of other like organisms. They lobbied widely among scientific colleagues to convince others that Bastian was at best a poor experimenter and at worst a fraud and a cheat. As mentioned above, Bastian, for his part, found it much more difficult to believe that life could survive the boiling temperature for more than a minute or two, than to believe (especially since he saw it as a logical necessity of continuity in nature and of evolutionary science) that the transition in stages from

Figure 4 Tyndall's dust-proof chamber for carrying out spontaneous generation experiments. Courtesy of the Royal Institution, London.

nonliving to living matter should be possible. A noted physiologist, John Burdon Sanderson, observed Bastian's technique carefully and reported that it was up to high scientific standards.

Huxley, in a famous address to the British Association for Advancement of Science meeting at Liverpool in September 1870, moved to gain the rhetorical upper hand in the debate by defining the terms. He defined 'biogenesis' to mean life only from other life. The opposite belief he termed 'abiogenesis' and began to argue that it very well might be possible, even probable, but only in the conditions of the primitive earth. This convenient dualistic terminology was rapidly picked up by contemporaries and propagated in textbooks. Given this, it is more than a little ironic that Huxley had hijacked the term 'biogenesis' from Bastian, who was using it up until that time to mean exactly the opposite, that is, spontaneous generation (After this, Bastian substituted the term archebiosis, but it never caught on as Huxley's terms did.). Also important, it is from this time that all discussion of the origin of life question began to be pushed more and more into the distant past. Only after Huxley's talk, for example, did Darwin advance the argument that if spontaneous generation had occurred in the earth's distant past, it would no longer be possible after the evolution of the first heterotrophs, since they would consume any organic molecules that formed before those could assemble into a new organism.

Those opposed to both evolution and spontaneous generation had a simpler solution. The physicist William Thomson, Lord Kelvin, for example, responded to both Huxley and Bastian in his own Presidential Address to the BAAS in 1871. He suggested that the germs of life might have originally been brought to earth from another world via a meteorite. To those demanding a completely naturalistic origin of life, of course, this merely pushed the question back a step to some other planet.

Beginning in the autumn of 1876, Tyndall began to have difficulty with the experiments carried out in his dust-free cabinet. Infusions that had been sterilized by only 5 minutes' boiling a year earlier now could not be sterilized even after hours of boiling. In 1876, the discovery by the German botanist Ferdinand Cohn that certain species of *Bacillus*, especially common in hay and in cheese (and in infusions made from these that showed microbial growth after extended boiling), were capable of producing heat-resistant endospores was taken to explain why Bastian's infusions were full of microbial growth after boiling, and upon being handed a copy of Cohn's article Tyndall immediately adopted this stance to explain his own recent difficulties.

Tyndall struggled for several months and finally discovered that sterility could be achieved by repeated short boilings, followed by a period of allowing the remaining spores to germinate. This process came to be known as 'fractional sterilization' or 'Tyndallization'. This was largely superseded with the development of the autoclave in the 1880s. Equally interesting from a historical point of view is that though this rapid about-face also showed that Tyndall and Huxley had been wrong that Bastian must be a sloppy, incompetent experimenter, that is precisely the version of Bastian (and most spontaneous generation advocates) that

has usually gone into the textbooks until quite recently. The sole exception was Pasteur's student Emile Duclaux, the only contemporary writer among the winners who credited Bastian's perseverance in sticking to his experimental results with the value that it truly had, that is, that without the goad of Bastian and his popularity, Pasteur, Cohn, and Tyndall might never have discovered that they were wrong about the existence of bacteria in boiled hay infusions, and thus been led to realize that heat-resistant spores exist and require autoclaving or fractional sterilization to guarantee their being killed. Pasteur was a devout Catholic and never believed, to his dying day, the viewpoint favored by many modern origin of life hypotheses, that random or chance organization of materials could have formed life, even the very first living organisms.

Twentieth Century Ideas

The origin of life has continued to be a subject of active interest in the twentieth century, and, despite avoidance of the term 'spontaneous generation' since 1880, some modern concepts have resembled older ideas more than superficially. Beginning with Bastian (who revived experiments on spontaneous generation from 1900 to 1915), a number of investigators came to believe that the basic chemistry specific to the living was the chemistry of colloids. A burst of research in colloid chemistry from 1910 until the 1930s included many workers who believed that this avenue would lead to understanding the simplest combination of materials to cross the boundary from nonlife to living matter. Among these were biochemists Benjamin Moore and Albert Mary, bacteriologist Arthur I. Kendall, the Mexican biologist Alfonso Herrera, and medical doctor and researcher George Crile. Geneticist H. J. Muller suggested that the first chemical assembly of a gene should be considered the origin of life, though this still suggested a sudden origin of life from nonlife, perhaps the most central idea implicit in the doctrine of spontaneous generation. The Russian biochemist A. I. Oparin proposed instead a gradual chemical evolution of life, probably proceeding through the intermediate stage of coacervates. Research into life's origin had lost none of its larger associations: the issue still attracted researchers with anticlerical leanings (Herrera was one) as well as affiliations with radical, even Communist political beliefs. J. B. S. Haldane and J. D. Bernal did research in the field and were avowed Communists, as was Muller until the late 1930s. Furthermore, Oparin and Wilhelm Reich explicitly credited the philosophy of dialectical materialism as having been crucial to their origin of life research programs.

Research on viruses, particularly Wendell Stanley's crystallization of tobacco mosaic virus in 1935, lent credence for a time to the idea that a virus might be the simplest 'living molecule'. In addition, after the rise of molecular biology and the discovery of the Watson-Crick DNA structure, many considered Muller's idea of "the gene as the origin of life" more likely. The Urey-Miller experiment, published just 3 weeks after Watson and Crick's paper on DNA, lent further support to the notion that the building blocks of life could have assembled very rapidly. In that experiment, an electrical discharge passed through a mixture of steam, hydrogen, methane, and ammonia in a sealed container produced amino acids and other organic compounds after only a few days. Throughout the 1950s and 1960s, such views were in tension with those of Oparin and his students in the Soviet Union, that the process of chemical evolution was a more gradual one, with no single decisive 'living molecule'. Cold War and anti-Lysenkoist hostilities were involved, as any scientific theory openly lauding dialectical materialism was seen as suspect in the West in the aftermath of Lysenko's takeover of Soviet genetics. The involvement of NASA as a major patron for origin of life research, beginning in 1960, led to the funding of a wide variety of approaches, including gradual evolution models as well as sudden, gene-based models; 'protein-first' or 'metabolism-first' as well as 'nucleic acid-first' or 'information-first' models. This work took place under the rubric of 'exobiology' (broadened and renamed 'astrobiology' in the late 1990s).

Thus, 'spontaneous generation' has been considered a dead-end, disproven belief since 1880 or so. But, despite the dropping of the older term, the conceptual continuities between modern and older origin of life ideas, particularly for abiogenesis in the earth's distant past, are in some ways as interesting as the discontinuities. The continued association of these ideas with larger philosophical and political concerns is also a striking feature of their history well into the twentieth century.

Glossary

Biofilm Sessile microbial communities consisting of an accumulated mass of bacteria, extracellular matrix molecules, and secreted bacterial products that aid in adherence to biopolymers and other solid surfaces.

Capsule Polysaccharide outermost layer of the cell. Production imparts a viscous slimy look to colonies.

cell wall One of the outer layers of the bacterial cell that protects the cell from osmotic perturbations and provides mechanical protection to the fragile cellular membrane.

Endonuclease Enzymes that have specific binding sites of varying complexities at which they sever phosphodiester bonds of DNA.

MSCRAMM (Microbial surface components recognizing adhesive matrix molecules) Proteins involved in the establishment of infection via the initial attachment of bacteria to host molecules such as elastin, collagen, fibrinogen, and fibronectin.

Plasmid Autonomously replicating small extrachromosomal DNA molecules.

Superantigen Any of a number of proteins that elicit a massive T-cell receptor V β -restricted primary response.

Nomenclature

CA-MRSA	Community-acquired MRSA
CDC	Centers for Disease Control
CHEF	Clamped homogeneous electrophoretic field
CoNS	Coagulase-negative staphylococci
HA-MRSA	Healthcare-associated MRSA
IFN- γ	Interferon- γ
MHC II	Major histocompatibility complex class II
MRSA	Methicillin-resistant <i>Staphylococcus aureus</i>
MSCRAMM	Microbial surface components recognizing adhesive matrix molecule
NCBI	National Center for Biotechnology Information
PIA	Production of a slime substance
PVL	Panton-Valentine leukocidin
RFLP	Restriction fragment length polymorphism
SE	Staphylococcal enterotoxin
SSSS	Staphylococcal scalded-skin syndrome

Defining Statement

The staphylococci are important bacterial pathogens that can infect both animals and humans and are responsible for numerous hospital- and community-acquired infections yearly. Staphylococcal infections result in a significant burden both economically and clinically for a variety of reasons, including virulence factors, increasing antibiotic resistance, and lack of effective vaccines.

Taxonomy

The genus *Staphylococcus* is defined in *Bergey's Manual of Determinative Bacteriology* as a member of the family *Micrococcaceae*. According to the most recent approved list from *Bergey's Manual* (9th ed.), there are presently 49 recognized species of staphylococci (Table 1),

[☆]Change History: February 2015. AF Gillasp, JJ Iandolo, Y-W Tang, and CW Stratton updated Section text and added references.

This article is an update of A.F. Gillasp, J.J. Iandolo, *Staphylococcus*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 293–303.

	<i>S. stepanovicii</i>
	<i>S. succinus</i>

22 of which are indigenous to or have been shown to colonize humans; the remaining species have been isolated from various animal (including one primate species), plant, or food specimens. Staphylococci are Gram-positive cocci 0.7–1.2 μm in size that occur singly and in pairs in liquid media and in tetrads and clusters when grown on solid media. Over the years, they have been characterized by their variety of colonial, morphological, and biochemical activities that have resulted in description of several biotypes of variable stability. They are aerobic or facultatively anaerobic, catalase-positive, and capable of generating energy by respiratory and fermentative pathways. These organisms are nutritionally fastidious with complex nitrogen requirements. Most species require several amino acids, vitamins (thiamine and niacin), and uracil (to grow anaerobically) for growth. In complex, nutritionally complete growth media, the organism is able to grow at generation times of ≤ 20 min, a rate comparable to that of *E. coli*.

At the molecular level, the genus can be distinguished from other members of the *Micrococcaceae* by the low GC content of its DNA, which ranges from 30% to 38%, the presence of teichoic acid in their cell wall, and their ability to tolerate extremely low water activities. *Staphylococcus aureus* is routinely cultured at a_w of 0.88 (15% NaCl) and has been reported to grow at water activity levels as low as 0.83 (saturated NaCl solution). Anaerobically, tolerance to low a_w is less with the limit at 0.90. The normal habitat of these organisms is the skin, skin glands, and mucous membranes of warm-blooded animals. However, staphylococci can be isolated from a variety of sources that include soil, dust, air, water, and food and dairy products. As a result they present a food and water public health hazard as well as an infection risk.

Cellular Structure

Cell Wall

The cell wall of *Staphylococcus* is a thick, electron-dense structure that provides great mechanical support to the cell. It is composed of a giant polymer consisting of peptidoglycan complexed with teichoic acid and other surface proteins described elsewhere in this article. The cell wall is a heteropolymer consisting of glycan chains cross-linked through short peptides. The repeating unit in the glycan backbone is β -1,4-*N*-acetylglucosamine and *N*-acetylmuramic acid (muramic acid). About 60% of the *N*-acetylmuramic acid residues are O-acetylated. The high level of O-acetylation makes the staphylococcal cell wall resistant to lysozyme digestion, therefore making this genus unique from most other bacteria. In fact, lysis of the cell wall under laboratory conditions is only efficient when the staphylococcal endopeptidase, lysostaphin, is added to cultured cells. Lysostaphin is produced by *S. simulans* and specifically cleaves the pentaglycine crossbridges found in the staphylococcal peptidoglycan. In *S. aureus*, adjacent polypeptides are cross-linked by pentaglycine crossbridges between the ϵ -amino of lysine and C-terminal D-alanine, whereas in other species, the composition of the crossbridge is variable. The carboxy group of muramic acid is substituted by an oligopeptide that contains

alternating L- and D-amino acids (L-alanine, D-glutamine, L-lysine, D-alanine, D-alanine). The teichoic acid component is linked to the D-alanine component of the mucopeptide by α - or β -glycosidic linkage through N-acetyl-D-glucosamine. In *S. aureus*, the teichoic acid backbone is ribitol based whereas in *S. epidermidis* it is glycerol based. In other species, glycerol teichoic acids are more common than their ribitol counterparts. These highly charged immunogenic cell wall components have been found to play a role in *S. aureus* nasal colonization, biofilm formation, and susceptibility to vancomycin and other glycopeptides.

Capsule

Capsule production has been shown to occur *in vivo* and *in vitro* for both *S. epidermidis* and *S. aureus*. For *S. epidermidis*, there have been at least three different capsular polysaccharide types identified in the literature. In contrast, 11 capsular polysaccharide serotypes have been described for the highly virulent species, *S. aureus*. The most common occurring serotypes among clinical isolates are types 5 and 8. The main components of the capsules are N-acetylaminouronic acids and N-acetylfucosamine. The genes for capsule production have been identified and are located in a single operon. The production of a capsule renders the staphylococci resistant to host defenses such as opsonization and phagocytosis. However, antibodies to capsular polysaccharides can neutralize the antiphagocytic properties of the capsule and opsonize the cell for phagocytosis. Opsonization has made the capsule a prime target in the search for an effective staphylococcal vaccine.

Several staphylococcal species, particularly *S. epidermidis* and *S. aureus*, have been shown to produce biofilms, and capsule production has been shown to be of particular importance during biofilm formation by aiding in adherence to biomaterials such as indwelling medical devices. A trademark of staphylococcal biofilm formation is the production of a slime substance (PIA), which is a polysaccharide composed of β -1,6-linked N-acetylglucosamines with partially deacetylated residues giving them a positive charge. Once bacterial cells are within this slime, they are protected from the host's immune defenses and are resistant to other treatments such as antibiotics. PIA is not the only component that has been shown to contribute to biofilm production under certain conditions, and research in this area continues. Recent investigations have shown that the presence of staphylococcal biofilm actively shifts host immunity towards an anti-inflammatory, pro-fibrotic response that favors staphylococcal persistence. *S. epidermidis* is the primary cause of catheter-associated staphylococcal infections and is a primary producer of biofilms. *S. aureus* biofilms have also been shown in patients with diseases such as osteomyelitis and endocarditis. Biofilm production in the staphylococci has been shown to be multifactorial and appears to be a bacterial survival mechanism when cells are exposed to sublethal levels of antibiotics and/or other stressful environmental conditions (i.e., limited nutrients, changes in temperature, oxygen limitation). It is also important to note that large phenotypic variations in biofilm production exist, with some isolates incapable of biofilm formation regardless of culture condition and others being hyperproducers under a specific set of conditions. Continued focus on understanding all of the components involved will give us more insight into chronic staphylococcal infections, especially those involving medical devices, and may lead to more efficient treatment of these diseases.

Molecular Structure

Genome

Presently, the genomes of multiple members of the genus *Staphylococcus* have been completely sequenced. These sequenced genomes include strains of *S. aureus*, *S. epidermidis*, *S. haemolyticus*, and *S. saprophyticus*. The genomic data for each of these projects are freely available on the World Wide Web at the National Center for Biotechnology Information (NCBI) website.

In all cases, the genome is circular and ranges from 2.49 Mb (*S. epidermidis*) to 2.9 Mb pairs (*S. aureus* strains). Table 2 shows a summary of the information obtained from the first 18 completed staphylococcal genome projects. Consistent with the *Micrococcaceae* family, all 18 of the isolates have a low GC content ($\sim 33\%$). The sequenced strains also exhibit a high amount of diversity within this genus, with some species and strains having acquired resistance to the antibiotics methicillin and/or vancomycin and some containing extrachromosomal elements called plasmids that most often contain additional genes that can contribute to pathogenesis. Among the sequenced isolates, the number of plasmids present varies from 0 to 3 and the size of these elements varies as well. Genetic and sequence data available indicate that in addition to the normal complement of housekeeping genes, the chromosome contains many accessory genetic elements that are not necessary for growth under laboratory conditions.

In *S. aureus* strains, pathogenicity islands SaPI1 and SaPI2 have been described and have been shown to encode virulence factors such as the toxic shock syndrome toxin gene, staphylococcal enterotoxin B, and as well as resistance to methicillin. In strains that do not contain SaPI1 or SaPI2 there are no allelic counterparts for these genes. The genes and overall genomic organization of *S. aureus* bear a striking resemblance to the genome of *Bacillus subtilis* such that the organism has been called a morphologically degenerate form of *Bacillus*. In addition, the genomic organization of the *S. aureus* strains sequenced thus far has been shown to be highly similar. Specifically, there is a genomic 'backbone' common to all *S. aureus* strains containing varying numbers of genes that may contribute to antibiotic resistance, tissue tropism, and virulence. Comparison of the two sequenced *S. epidermidis* strains showed that the overall genomic organization is similar, with two relatively small areas of inversion apparent when the two genomes are aligned to each other at the nucleotide level. Figure 1 shows alignments at the nucleotide level for two representative *S. aureus* strains as well as the two *S. epidermidis* strains. Alignment of *S. haemolyticus* and *S. saprophyticus* to *S. aureus*, *S. epidermidis*, or to one another showed little or no conservation of gene order. However, at the level of protein content, members of the genus are highly similar and this is illustrated graphically in Figure 2. Specifically, when the translated sequences for several of the sequenced staphylococcal

Table 2 Completed staphylococcal genome project

Organism	Genome size (Mb)	Plasmid(s) size (kb)	% GC	Number of predicted genes	MRSA/VRSA

<i>S. epidermidis</i> strain ATCC12228	2.49	N/A	32.09	2419	MRSA
<i>S. epidermidis</i> strain RF62A	2.64	27.3	32.14	2665	MRSA
<i>S. haemolyticus</i> strain JCSC1435	2.68	N/A	32.79	2678	MRSA
<i>S. saprophyticus</i> strain ATCC15305	2.57	38.5, 16.3	33.18	2514	MRSA

Figure 1 The left panel shows alignment of *S. aureus* strains NCTC8325 and USA300 at the nucleotide level. The solid red line indicates that the two strains are virtually identical in genomic organization. Right panel shows the alignment of *S. epidermidis* strains ATCC12228 and RP62A. The break in the red line and the shorter green lines show that although the two strains are overall highly similar in organization, there are some differences. Differences are believed to be due to the presence or absence of such things as bacteriophage and pathogenicity islands.

Figure 2 Comparison of proteins encoded within 13 members of the genus *Staphylococcus*. Completed genomes used in the above comparison are listed starting with the outermost circle: *S. aureus* strain NCTC8325, *S. aureus* strain COL, *S. aureus* strain USA300-FPR3757, *S. aureus* strain MW2, *S. aureus* strain Mu50, *S. aureus* strain MSSA476, *S. aureus* strain N315, *S. aureus* strain MRSA252, *S. aureus* strain RF122, *S. haemolyticus* strain JCSC1435, *S. epidermidis* strain ATCC12228 and *S. epidermidis* strain RP62A. Using NCTC8325 as the reference strain resulted in a total number of 2892 predicted proteins used for the comparison. Of the 2892 proteins used, 1775 were found to be present in all other genomes, with 2756 present in at least another genome and only 136 not found in any other of the comparison genomes.

genomes are compared (at a minimum cutoff level of $\geq 40\%$ similarity) to one another using *S. aureus* NCTC8325 as the reference strain (since this strain has the largest number of predicted open reading frames), the level of protein similarity is 61.4% across the entire group. Of course, the level of similarity is slightly higher when the same type of comparison is done within species (85–92%) but the overall similarity at the genus level is still highly significant. For perspective, the same comparison done with *S. aureus* NCTC8325 and *B. subtilis* showed only 59% overall protein similarity.

In addition to large pathogenicity islands the staphylococcal genome (especially *S. aureus*) typically contains multiple instances of transposable elements such as *Tn551*, insertion sequences IS256, IS257, IS1181, and others. *S. aureus Tn551* and its close relative *Tn917* have been extensively utilized to generate knockout mutations in staphylococci, many of which have been mapped and localized near other genes. The primary strain of *S. aureus* used for genetic manipulation and gene discovery is NCTC8325 and its derivatives. Also known as PS47, this is the propagating strain for the typing bacteriophage $\phi 47$ and is a member of phage group III. It is routinely used to generate batches of bacteriophage used for typing purposes and is lysogenized by three temperate phage: $\phi 11$, $\phi 12$, and $\phi 13$. A derivative (8325-4) that has been cured of all demonstrable phage was originally developed as the prototype strain whose genome was used to build a circular map based on genetic and physical parameters. With the advancements in whole-genome sequencing technology this map is no longer the primary resource used for mapping and typing experiments. However, in the absence of sufficient genomic information, this type of mapping is still used to examine new *S. aureus* isolates and to determine basic lineage information for these isolates.

Plasmids

As mentioned above, the staphylococci are also endowed with a generous array of plasmids ranging in size from a few kilobases to 40–50 kb. In fact, typically one or more plasmids are found in most staphylococcal clinical isolates, including both *S. aureus* and the coagulase-negative staphylococci. The inability of two plasmids to coexist in a single host indicates that they have the same replication control functions and are incompatible and assigned to the same incompatibility group (*inc* group). Thus far, there are 15 recognized incompatibility groups (*inc* 1–15), but the replication characteristics of some staphylococcal plasmids remain undetermined and they are still unclassified. The 15 *inc* groups have been further divided into three main classes (I, II, and III) with a fourth class that contains the pSK639 family of plasmids. The four groups are based on both physical and genetic organization as well as functional characteristics. Some staphylococcal plasmids are cryptic but most carry resistance determinants and some carry other virulence factors such as toxins. Group I plasmids are relatively small plasmids (typically <5 kb) that replicate by the rolling circle mechanism. They are of a low copy number (10–60 copies per cell) and usually do not contain any transposons or mobility factors. The pSK639-type plasmids (group IV) are of intermediate size (8 kb range) in comparison to group I and II plasmids. The prototype plasmid for this group, pSK639, was originally isolated from *S. epidermidis* and was later found to be in some strains of *S. aureus*. pSK639-like plasmids carry only one resistance determinant and may harbor IS elements and/or transposons as well. The origin of replication appears to be similar to the theta replication system and unlike the group I plasmids they typically contain mobility factors. Group II plasmids are larger in size than the pSK639 group and are also known to carry multiple resistance factors. They range in size from 15 to 40 kb and have low copy number (~5 copies per cell). Along with the capability of encoding for several resistance factors on a single plasmid, they also contain transposable elements and like the pSK group replicate via theta mode. Group II plasmids generally confer resistance to β -lactam antibiotics and heavy metals and are also the group responsible for conferring methicillin resistance. Plasmids in group III are typically of the largest size (30–60 kb) and are conjugative in nature. They are found in both coagulase-negative staphylococci and *S. aureus* and tend to carry a number of resistance determinants. The replication region is similar in sequence to the group II plasmids and similarly they contain multiple copies of IS elements and transposons. Although conjugation of these staphylococcal plasmids is not completely understood, it is known to require cell-to-cell contact on a solid surface; also, there is no pilus as described in conjugation of *E. coli* plasmids. Vancomycin resistance at both high and intermediate levels has been shown to be encoded on group III plasmids, and there is evidence suggesting that the resistance marker and the plasmid have been acquired through transfer from the enterococci. It is widely held that plasmids are exchanged among staphylococci, enterococci, streptococci, and bacilli, accounting for the presence of the same or similar plasmids in each genus.

Staphylococcal Bacteriophages

S. aureus was among the first organisms used to demonstrate the existence of bacteriophages. Bacteriophages have also been found in coagulase-negative staphylococci. The vast majority of phages in coagulase-positive and coagulase-negative staphylococci are double-stranded DNA phages belonging to the *Siphoviridae* family of the *Caudovirales* order. Intensive study of staphylococcal bacteriophages has led to the establishment of a complex method of bacteriophage typing of disease isolates identified in epidemiological investigation. A panel of 21 bacteriophages called the International Typing Series of Bacteriophages is used to define strain types by specific patterns of susceptibility to these typing phages. Phage typing led to the identification of five strain groups (I–IV and miscellaneous). Most pathogenic strains belong to groups II and III, but all phage groups are capable of causing disease. More recently, phage typing has lost favor because of the finding that the standard bacteriophage-propagating strains carry temperate bacteriophages that are distinct from the typing phage they propagate. The phage preparations derived from these strains are therefore mixtures of several bacteriophages. In fact, virtually all strains of *S. aureus* are lysogenized by at least one bacteriophage and many carry multiple temperate phage in their genome. Some of the lysogenizing phage carry additional genes that they bring in to the recipient strain and alter its phenotype by inserting into the genome at specific attachment sites located within genes.

Both negative conversion (the inactivation of expressed genes (e.g., lipase and β -toxin)) and positive conversion (the introduction of newly expressed genes (staphylococcal enterotoxin A and staphylokinase)) are common occurrences in staphylococci. Temperate bacteriophage have been shown to alter the restriction pattern of the genome by introducing additional restriction sites that produce restriction fragment length polymorphisms (RFLPs) when analyzed by clamped homogeneous electrophoretic field (CHEF) gel electrophoresis. The creation of additional sites has caused ambiguities and difficulties in establishing clonal derivations in many epidemiological investigations of disease outbreaks. Phage typing of the staphylococci has also been made more difficult because not all methicillin-resistant *S. aureus* (MRSA) isolates come under the defined phage categories. Recently, studies have been performed to identify new phage to recognize this group as well as to identify alternative typing methods that may be more reliable for all kinds of isolates.

Bacteriophage are also thought to play a major role in the transmission of virulence factors and in the occurrence of genetic rearrangements. They are responsible for the only naturally occurring means of genetic exchange in the staphylococci. The first reports of transduction in staphylococci occurred in 1960 and concerned the transmission of resistance to penicillin. Since then many detailed studies of the transductional transmission of genes have been published. Most staphylococcal bacteriophage are generalized transducers, capable of transferring ~40–45 kb of DNA (a headfull) to a suitable recipient strain. DNA is packaged from PAC sites that are randomly dispersed around the genome.

Bacteriophage also play a role in transformation after induction of competence by Ca^{2+} treatment. Both plasmid and chromosomal DNA can be transferred by transformation, albeit at low frequency. In order for the transforming DNA to be recombined, it is necessary that the recipient strain be lysogenized by a serogroup B bacteriophage (there are 12 serogroupings). Other procedures, such as electroporation, enjoy limited effectiveness for plasmid transfer, but are not useful for transfer of chromosomal genes.

Coagulase-Negative Versus Coagulase-Positive Staphylococci

The primary players in human infection are actually *S. aureus*, *S. lugdunensis*, *S. epidermidis*, and, to a lesser degree, *S. saprophyticus*. These species are basically identical except for the ability of *S. aureus* to produce the fibrinogen clotting substance coagulase. The coagulase-negative species, *S. lugdunensis* and *S. epidermidis*, are largely commensal and can be isolated in high numbers from all areas of human skin. Likewise, *S. aureus* can be a colonizer of human skin and nares, but is more capable of causing infection if the microorganism should gain entrance to subcutaneous human tissues. It was proposed by Baird-Parker that coagulase distinguished pathogenic from nonpathogenic species and this differentiation was used until the mid-1970s. However, recent evidence has shown that coagulase-negative staphylococci (CoNS) are a major cause of wound infections and infections caused by foreign bodies including intravascular catheters, peritoneal dialysis catheters, prosthetic heart valves, joint prostheses, pacemaker electrodes, and fluid shunt systems. Therefore, coagulase is no longer considered an exclusive indicator of pathogenicity but is still used as a method for species identification.

S. lugdunensis, *S. epidermidis*, and *S. saprophyticus* are ultimately distinguished from *S. aureus* based on the lack of coagulase activity. Of the staphylococci that are of medical importance, *S. aureus* is the only one that is coagulase-positive. Two other staphylococcal species (*S. hyicus* and *S. intermedius*) are also coagulase-positive but are rarely isolated from human infections. *S. aureus* also differs from the other clinically relevant members of this genus in that it is β -hemolytic on blood agar and forms large, yellow-pigmented colonies upon growth.

In a clinical setting it is imperative that the particular species involved is correctly identified as this plays a role in treatment options. All staphylococci are Gram-positive, coccoid, and grow as clusters in culture. *S. saprophyticus* grow as small, nonhemolytic, white colonies on blood agar and are isolated almost exclusively from urinary tract infections in young, sexually active females. *S. epidermidis* is the most abundant organism found on the skin of humans and is characteristically seen as nonhemolytic, white colonies on blood agar plates. *S. lugdunensis* is also found on the skin of humans and can cause infections, including endocarditis on a native valve, that are identical to those caused by *S. aureus*. Only half of the 32 CoNS have been found in humans and this group can be further divided based on whether they are resistant or sensitive to novobiocin. *S. epidermidis* is novobiocin-susceptible while *S. saprophyticus* is novobiocin-resistant. Clinical manifestations of coagulase-negative staphylococci are more subtle and nonspecific as compared to *S. aureus* and are also less likely to be fatal. However, with *S. epidermidis* in particular, these infections typically involve indwelling medical devices and are most often chronic. Indeed, the large majority of CoNS infections are nosocomial and strains isolated from humans typically produce an inducible β -lactamase, with 60–80% of them resistant to methicillin.

Pathogenesis and Disease

Before discussing staphylococcal pathogenesis it is important to note the difference between colonization and infection. Colonization can be defined as the presence of an organism in or on a particular body site in the absence of signs and symptoms of disease. Colonizing organisms can typically cause disease if they spread to a different site on the same individual (i.e., from skin to bloodstream) or are transferred to a more susceptible host. Infection is defined as the ability to isolate a replicating organism from a disease site within the host. Infection may result in immediate signs and symptoms or may be clinically unapparent. However,

infection by an organism does eventually result in some level of inflammation within the host. Interestingly, although a host can become infected as soon as a pathogen invades, in many cases colonization precedes infection.

Carriage

Staphylococci are one of the major groups of organisms that inhabit the skin of mammals. Usually, several different strains are found on the same host. They may be present as transient contaminants, short-term replicating residents, or as long-term colonizers that persist for long periods. The majority of species are opportunistic pathogens that become infectious when the skin or mucous membranes are compromised by trauma, inoculation by needle, or direct implantation of medical devices (foreign bodies). Staphylococci are then able to attach, colonize, and produce toxic substances that destroy host tissues.

As stated previously, the majority of staphylococcal disease is due to infection with the coagulase-positive species *S. aureus*, which is considered an opportunistic pathogen because it is not uncommon for healthy individuals to carry the organism either persistently (10–35% of population) or intermittently (20–75%) in the anterior nares. Although colonization is not uncommon, it is also not ubiquitous among humans. In fact, recent studies have shown that 5–50% of people never carry *S. aureus*. In addition, the higher carriage rates are often related to the level of exposure; with healthcare workers often more likely to be colonized than individuals in the general population. Most often, carriers of *S. aureus* show no signs of disease; however, this organism can cause severe, even life-threatening disease under certain circumstances.

Disease Types

Species of *Staphylococcus* are the leading cause of nosocomial infection. Each year about 2 million hospitalizations result in nosocomial infection and ~50% are due to *S. aureus* and *S. epidermidis*. Community-acquired infections have a similar incidence rate. A predisposing condition has been the acquisition of multiple drug resistance by *S. aureus* (MRSA), which has caused the incidence of nosocomial and community-acquired infection to increase steadily since the 1960s. Prior to the 1990s, MRSA infections were associated with hospitals or other healthcare facilities; such MRSA isolates were usually resistant to multiple antibiotics and susceptible only to vancomycin and rifampin. These MRSA strains have been characterized as healthcare-associated MRSA (HA-MRSA). Beginning in the early 1990s, infections due to MRSA was seen in patients who had no previous healthcare exposure; these strains were resistant to beta-lactam agents but were often susceptible to other antibiotics such as clindamycin and trimethoprim-sulfanethoxazole. These MRSA strains have been characterized as community-acquired MRSA (CA-MRSA). Infections initially seen in the United States were due to CA-MRSA strains of ST1 lineage, which were also characterized as USA400 based on PFGE typing. CA-MRSA strains were found to possess an SCCmecA element (SCCmec IV) that was distinct from the elements I – III seen in most healthcare-associated MRSA. These CA-MRSA strains also contained genes encoding the Panton-Valentine leucocidin (PVL); PVL damages polymorphonuclear leukocyte membranes via a beta-barrel pore-forming mechanism. Subsequently the USA400 strain of CA-MRSA was replaced by another clone, ST8 (USA300); the USA300 strain now accounts for almost 90% of the CA-MRSA isolates in the United States. Of note is that the USA300 strain contains an SCCmec element that is smaller than SCCmec I – III and possesses fewer resistance genes.

The primary mode of pathogenesis for *S. epidermidis* is via colonization of biomedical devices such as indwelling catheters as a result of biofilm formation on the surface of these biomaterials. Although *S. aureus* causes a wide variety of pyogenic and toxin-mediated diseases, *S. epidermidis* rarely causes pyogenic disease in the immunocompetent host and there is very little evidence to suggest that it is responsible for toxin-mediated disease. Outside of indwelling medical device infection, *S. epidermidis* is primarily seen in intravenous drug users and immunocompromised patients such as premature newborns and individuals undergoing immunosuppressive therapy. The clinical manifestations associated with these groups are right-sided endocarditis and septicemia, respectively. Unlike *S. aureus* infections, there are typically no fulminant signs of infection and the clinical course is therefore more chronic in nature.

S. lugdunensis is part of the normal human skin flora and is an infrequent, but not rare, cause of human infections. *S. lugdunensis* is an unusually virulent strain of coagulase-negative staphylococci and can cause aggressive infections similar to those caused by *S. aureus*. Indeed, these human infections include native valve endocarditis. The most common infections caused by *S. lugdunensis* are skin and soft tissue infections; such infections are often seen in the perianal, inguinal, or pelvic region. *S. lugdunensis* has also been associated with orthopedic infections involving prosthetic joints as well as osteomyelitis.

S. aureus is the most highly pathogenic organism of the staphylococci and has been isolated from infection sites involving virtually every tissue of the body. In general, three types of disease are usually associated with infection by *S. aureus*. These are characterized as superficial or cutaneous infections such as pimples, boils, and toxic epidermal necrolysis; systemic infections such as heart valve disease, bacteremia, and osteomyelitis; and toxinoses such as food poisoning and toxic shock syndrome.

Immunity

Immunity to staphylococcal infections is poorly understood. Normal healthy humans have a high degree of innate resistance to invasive infections. Experimental infections are difficult to establish in animals and require large inocula containing millions of organisms. In humans, the organism is able to colonize mucosal and epidermal surfaces with little resistance, and as long as they remain intact, these barriers are the main source of natural immunity to infection. After invasion, however, phagocytosis by polymorphonuclear leukocytes is the main humoral defense. Because of repeated exposure to *S. aureus* and *S. epidermidis* in natural

settings, antibodies to various components of the cell and its products (both cell surface and soluble) are prevalent in animals. Nevertheless, with the exception of toxic shock syndrome where antibody is an important factor in immunity, serological studies have not successfully related immunity and antibody titer. Moreover, prior infection fails to elicit immunity to reinfection. In spite of these drawbacks, vaccine research is being pursued strongly. Although there is currently no vaccine that stimulates active immunity in humans, a vaccine based on fibronectin-binding protein has been shown to confer protective immunity against mastitis in cattle. Among the vaccines being studied for use in humans, the most promising is a polysaccharide conjugate vaccine that was given Fast Track Status by the FDA in 2004 for the prevention of bacteremia in certain at-risk patient populations; however, the vaccine failed to reduce the incidence of *S. aureus* infections when used in clinical trials.

Identification

The clinical laboratory must be able to identify *S. aureus* quickly and accurately. Many types of clinical samples have been utilized for detection. Samples that are heavily contaminated with other bacterial flora (i.e., nasal, skin, or wound specimens) can be grown on solid media or liquid media containing various selective agents that exploit the resistance of staphylococci to NaCl, chemicals such as potassium tellurite and lithium chloride, or antibiotics. Suspect colonies from the primary isolation are then subjected to antibiotic sensitivity determination to provide treatment alternatives. As mentioned above, coagulase determination, an important consideration for treatment decisions regarding CoNS strains, is usually carried out. A variety of other phenotypic markers can be tested if further characterization is desired. These include α - and β -hemolysins, nuclease, proteases, lipase, protein A, and the determination of specific toxins.

Treatment

More than 95% of patients with *S. aureus* infections worldwide do not respond to first-line antibiotics such as penicillin and ampicillin. These strains have been routinely treated with methicillin, but resistance appears in a large number of infections (HA-MRSA and CA-MRSA). Vancomycin is the most effective treatment for multiresistant strains, but the recent emergence of vancomycin resistance in staphylococci poses a critical problem to effective treatment of these infections. The emergence of strains that are resistant to multiple antibiotics, especially the recent appearance of vancomycin resistance, has spurred renewed interest in antibiotic discovery and vaccine therapy. CA-MRSA strains are often treated with clindamycin, doxycycline, or trimethoprim-sulfamethoxazole. New drug targets are being investigated to devise novel families of antibiotics. Methicillin resistance is not limited to *S. aureus* and all of the other staphylococcal species that have been sequenced to date are isolates that carry the genes conferring resistance to this antibiotic and some contain plasmids that confer resistance to other compounds used for treatment.

Antibiotic Resistance and MRSA

Nosocomial infections with HA-MRSA have been identified as a problem since the 1960s, with ~20% of bloodstream infections being due to *S. aureus*. As many as 64.4% of hospital onset *S. aureus* infections reported in US intensive care units were due to HA-MRSA. These types of infections are not only important due to the danger they pose to the patient but they also result in longer hospital stays, higher mortality, and increased costs for alternative treatments. Until recently, the focus of MRSA infections was limited to those that were nosocomial (hospital onset) in nature, with little or no surveillance activity for community-acquired MRSA (CA-MRSA). This was due in large part to a much lower incidence of CA-MRSA in relation to hospital-acquired infections. However, in a study carried out by the US Centers for Disease Control (CDC) to estimate the burden of invasive MRSA infections in the United States in 2005, CA-MRSA was identified as a major source of infection. Of the almost 8987 cases of invasive MRSA that were reported, ~85% were related to recent hospitalization or were of hospital onset and 13.7% were classified as CA-MRSA. The study also showed that infection rates were highest in older patients (≥ 65 years), African Americans, and males. Interestingly, the group at lowest risk included young people ranging from 5 to 17 years of age. The study concluded that invasive MRSA affects certain populations disproportionately and that it is a major public health problem primarily related to health care. The researchers also stress the point that MRSA should no longer be confined to healthcare institutions, and that the incidence of CA-MRSA will most likely continue to increase.

There are multiple reasons that the staphylococci, especially *S. aureus*, have become antibiotic-resistant including overuse of antibiotics in humans, the presence of antibiotics in food and water supplies, and mutation and/or exchange of genes within the genus. Unnecessary prescriptions for antibiotics is one of the main sources contributing to staphylococcal (and other microorganisms) developing resistance. Decades of excessive antibiotic use for colds, flu, and other viral infections that do not respond to these drugs results in low-level exposure to these compounds by normal bacterial flora found in the host. This repeated exposure to sublethal concentrations results in the elimination of the majority of the resident bacteria and selects for spontaneously occurring mutants that are resistant to the antibiotic. Over time, the presence of the antibiotic has no effect on the organism and therefore they are resistant to killing by the drug when it is prescribed for actual treatment. Prescription drugs are not the only source of antibiotics. In the United States, antibiotics can be found in animal feeds especially for beef cattle, pigs, and chickens. The same antibiotics then find their way into municipal water systems when the runoff from feedlots contaminates streams and groundwater. However, antibiotics given in the proper doses to sick animals do not appear to produce resistant bacteria. Even appropriate antibiotic use can contribute to the increase in drug-resistant bacteria because they may not destroy every organism within the population. Bacteria

evolve rapidly; so those that survive treatment with one antibiotic are soon capable of resisting others. Bacteria mutate much more quickly than new drugs can be produced, which makes it possible for a given organism to become resistant to all available treatment options. In addition to mutation of genes, the staphylococci are adept at gene transfer via mobile genetic elements such as plasmids, phage, and transposons. By carrying and transferring antibiotic-resistant genes via these mechanisms, antibiotic resistance has become rampant within this group. Although there has not yet been a strain of *S. aureus* identified that is resistant to all of the available antibiotics, there are many that are resistant to the majority of drugs currently available. In fact, it is relatively uncommon for any given clinical isolate to be resistant to only one drug and almost all that are isolated are resistant to penicillin, which was the original drug used to treat most bacterial infections. More importantly, there are now multiple strains that have acquired resistance to what used to be the drug of last resort (vancomycin). Using vancomycin and other more aggressive forms of treatment contribute to the economic burden endured by the patient and hospital, and these types of treatments are also more physically demanding for the patient. For example, vancomycin is generally given in multiple intravenous doses over several weeks, which requires additional specialized care and a longer stay within the hospital. The drug itself often makes the individual feel even worse than before treatment began, with potential side effects including, but not limited to, kidney failure, temporary or permanent hearing loss, neutropenia, anaphylaxis, pain and inflammation at the injection site, severe stomach pain, diarrhea, and fever or chills.

Virulence Factors

Staphylococci produce a wide array of extracellular and cell surface proteins with a large number of these encoded on plasmids and other accessory elements. Because of this, different strains have been shown to exhibit a variable array of toxins, enzymes, and other factors. A list of some of these exoproteins is presented in Table 3. The extracellular proteins are subdivided into cell surface-oriented proteins and soluble proteins. All the exoproteins are translated as precursor proteins with signal peptides, which are removed at secretion. In addition, the cell surface proteins also possess a characteristic amino sequence motif (LPXTG) at the C-terminus, which precedes the membrane spanning region and serves as an anchor, linking the protein to the cell wall peptidoglycan. Both types of exoproteins are secreted by Type II secretory mechanisms involving the SecYEG pathway. With the exception of certain bacteriocins, there is no evidence to date that extracellular proteins are secreted by other secretory pathways.

Soluble Exoproteins

These include a wide array of toxins and enzymes such as food poisoning enterotoxins, exfoliative toxins, toxic shock syndrome toxin, hemolysins, coagulase proteases, lipases, and other enzymes. The exfoliative toxins are proteolytic and attack the epidermis of susceptible animals. Exfoliative toxins cause blistering skin diseases known as bullous impetigo and staphylococcal scalded-skin syndrome (SSSS). Three isoforms of exfoliative toxins (ETA, ETB, and ETD) have been identified in virulent strains of *S. aureus* and four isoforms have been shown to exist in the animal pathogen *S. hyicus*. Clinical manifestation of SSSS is typically seen in neonates and has been termed scalded skin syndrome due to the symptoms that occur culminating in areas of raw, red skin that resembles that of a first-degree burn. The enterotoxins have been shown to act at the interface between the stratum granulosum and stratum spinosum of the epidermis, thereby resulting in characteristic exfoliation of the skin. In other words, there is a loss of keratinocyte cell–cell adhesion in the epidermis. It was initially difficult to determine the mechanism of action for these toxins because purified forms of both ETA and ETB showed no direct protease activity toward multiple targets. However, recent studies have shown that the three isoforms of exfoliative toxins, ETA, ETB, and ETD, are glutamate-specific serine proteases and that ETA and ETB specifically cleave a protein in the epidermal interface called desmoglein 1. ETD has been shown to be encoded within a pathogenicity island and to play a slightly different role in the development of bullous impetigo and scalded skin syndrome disease.

The hemolysins are membrane-damaging proteins whose activity is mediated through pore formation or lipolytic action. The most studied of the hemolysins is α -toxin, which is toxic to a wide range of mammalian cells and is highly hemolytic for rabbit erythrocytes. It is also dermonecrotic and neurotoxic and is produced by almost all strains of *S. aureus*. β -toxin is made in high concentrations, particularly by animal strains of *S. aureus*, and is highly hemolytic for sheep erythrocytes but not rabbit red blood cells. This toxin exhibits phosphorylase C activity that requires magnesium but it has a limited range of activity due to specificity for sphingomyelin and lysophosphatidyl choline. The role of β -toxin in disease is not well understood but the fact that it is made at much higher levels in animal strains suggests that it may provide an advantage in animal hosts as opposed to humans. Another example of an *S. aureus* pore-forming toxin is the Panton–Valentine leukocidin (PVL), which is a cytotoxin that causes leukocyte destruction and tissue necrosis. PVL is encoded on a bacteriophage and has been associated with both staphylococcal skin and pulmonary infections. PVL-containing strains have also been isolated at a higher frequency from patients with severe cMRSA pneumonia and the presence of the toxin is much higher in strains that carry the SCCmecIV cassette than in strains that do not.

Another group of toxins that play a significant role in staphylococcal disease are the enterotoxins. The enterotoxins are responsible for the clinical manifestations of staphylococcal food poisoning and a septic shock-like illness. There are five major classical types of staphylococcal enterotoxins (SEs), and several new SEs or SE-like toxins have recently been identified. Ingestion of these toxins leads to severe gastroenteritis with emesis, nausea, and diarrhea. In addition, the SEs are resistant to extreme heat and are stable over a wide pH range besides being resistant to degradation by a variety of proteases. They are also classified as superantigens, a characteristic that is described in more detail below.

Table 3 Extracellular proteins of *Staphylococcus aureus*

<i>Protein</i>	<i>Gene locus</i>
Hemolysins	
Alpha toxin	Chromosome
Beta toxin ^a	Chromosome
Gamma toxin	Chromosome
Delta toxin ^a	Chromosome
Panton-Valentine leukocidin	Chromosome/pathogenicity island
Enterotoxins

Collagen-binding protein	Chromosome
Elastin binding protein ^a	Chromosome
Extracellular matrix-binding proteins ^a	Chromosome
Intercellular adhesion proteins ^a	Chromosome

^aDenotes virulence factors that are also present in *S. epidermidis*.

Several of the soluble exoproteins including enterotoxins, exfoliative toxins, and toxic shock toxin are superantigens due to their ability to stimulate mitogenic activity and cytokine production for a wide array of T-lymphocyte haplotypes. They are able to activate specific sets of T-lymphocytes by binding to major histocompatibility complex class II (MHC II) proteins. They bind to the variable region of the T-cell receptor β -chain. The activated cells proliferate and release cytokines/lymphokines, interferon- γ (IFN- γ), and interleukins. Because they exhibit this broad-based activity, they have been called superantigens. This activity is suspected to enhance virulence by suppressing the hosts response to staphylococcal antigens produced during infection. In addition to the factors discussed above, there are many staphylococcal enzymes such as lipase, nuclease, and proteases, and all are presumed to enhance invasiveness through tissue destruction.

Cell Surface Proteins

A major class of cell surface proteins are adhesins termed MSCRAMMs (microbial surface components recognizing adhesive matrix molecules). These molecules comprise the main adhesins of the organism and include collagen-binding protein, fibronectin-binding proteins, fibrinogen-binding protein, elastin-binding protein, clumping factor, and the matrix adhesin factor. There may be as many as 12 other surface proteins that contain membrane anchor domains and potentially qualify as MSCRAMMs. A second

group of cell surface proteins includes nuclease and protein A. Staphylococcal nuclease is a thermally stable endonuclease able to withstand boiling for 30 min without significant loss of activity. Protein A is able to bind to the nonantigenic F_c fragment of immunoglobulin G, causing the complex to precipitate. Its role in virulence is believed to be in escape from immune surveillance.

Regulatory Mechanisms

The expression of extracellular proteins is largely under the influence of a master genetic circuit called *agr* (accessory gene regulator). This signaling arm of the operon (AgrBDCA) is activated by a quorum-sensing mechanism that depends upon the accumulation of an activating octameric peptide (processed from the AgrD precursor by AgrB). The peptide triggers increased expression of the entire operon via an integral signal transduction pathway (AgrC, AgrA), upregulating production of the octomer and activating a second promoter that produces a unique regulatory molecule, RNAIII. RNAIII is the effector molecule for regulated protein expression. It is neither translated nor does it bind to the promoter regions of regulated genes. It presumably interacts with other genes, in an unknown way, as both a positive and negative regulator of exoprotein gene expression. RNAIII is required for the expression of soluble exoproteins and represses the expression of cell surface proteins. Because a threshold level of octapeptide is required for activation, RNAIII is not expressed until late in growth. Therefore, cell surface proteins are produced early, presumably to allow the organism to attach and colonize. The RNAIII-induced activation of soluble proteins genes results in a necrotic effect, allowing the organism to invade deeper tissues and become bacteremic. A second locus, *sarA*, modulates expression of the *agr* locus by binding to the promoter region of AgrBDCA. The *sarA* locus is transcribed from three different promoters (*sarP*1, P2, and P3) that are active at different times during growth. The major regulatory molecule encoded by *sarA* is a 14.5 kDa protein that has been shown to bind to the promoter regions for fibronectin-binding protein A, the collagen adhesion, protein A, and *agr*. It is reported that the *sarA* locus plays a role in transcription of over 100 different gene targets either by direct binding of upstream promoter regions or indirectly due to its effects on other regulatory loci including *agr*. Several *sar* homologues have been identified including *SarR*, *SarS*, *SarU*, and *SarY* that play a role in regulation of *SarA* and other factors. With the continued efforts aimed at whole-genome sequencing of staphylococcal isolates, many other regulatory systems that are not discussed in detail here have been identified and characterized. These include *Rot*, *SaeRS*, *SrrAB*, *ArlRS*, and *LytRS*.

Another important level of regulation of virulence is regulation of gene expression in response to environmental factors. It has been demonstrated that depending on the environment that the staphylococci encounter they can adapt by altering gene expression for a variety of systems. This is not unusual for bacteria and in fact the main environmental response system that has been described for *S. aureus* and *S. epidermidis* is the sigma B pathway. Sigma factors are bacterial proteins that enable specific binding of RNA polymerase to promoter regions within the DNA. The staphylococcal sigma B response is similar to that described for other Gram-positive pathogens such as *B. subtilis*. Sigma B is an alternative sigma factor that is activated under environmentally stressful conditions such as high salt levels, presence of ethanol, energy depletion, and low pH. Comprehensive studies in *S. aureus* have shown that sigma B regulates gene expression of some factors by directly binding to a specific site upstream of promoters and also by indirectly affecting upstream factors to gene expression. Some of the virulence factors that have been shown to be affected due to sigma B expression include coagulase, fibronectin-binding protein B, biofilm formation, and α -toxin. A change in resistance levels to some antibiotics that affect the bacterial cell wall has also contributed to overexpression of sigma B. It is important to note that some strains of *S. aureus* have a mutation in the sigma B activator (*RsbU*) that renders them sigma B defective. These strains are also capable of growing under environmentally stressful conditions, which suggests that there are additional systems that have yet to be identified and that must play a role in virulence factor expression.

Defining Statement

The primary natural habitat of *Streptococcus pneumoniae* on this planet is the nasopharynx of preschool age children, and antibiotics and vaccines not only combat pneumococcal disease but also drive the evolution of drug resistant and novel capsular types of this species. In this sense, humans are not only targets but also evolutionary partners of *S. pneumoniae* as well.

Guides to the *S. pneumoniae* Literature

Useful guides to the rapidly expanding literature on various aspects of the microbiology and infectious diseases of *Streptococcus pneumoniae* may be found in books listed at the end of this article which cover contributions to the field in the early and the more recent era.

Periodic updates on progress are also available through informal meetings of two groups of scientists: those interested primarily in pneumococcal molecular biology (EUROPNEUMO: European Meeting on the Molecular Biology of the Pneumococcus) and those interested in pneumococcal disease (ISPPD: International Symposium on Pneumococci and Pneumococcal Diseases). An international workshop that brought together scientists interested in the molecular biology and infectious diseases aspects of *S. pneumoniae* was held between September 23–29, 1996 in Portugal – organized by Herminia de Lencastre and Alexander Tomasz. The proceedings of this meeting were published in book form (In *Streptococcus pneumoniae* - Molecular Biology and Mechanisms of Disease - Update for the 1990s. A. Tomasz, editor. Mary Ann Liebert, Inc. publishers, New York). This ground-breaking meeting led to the foundation of the ISPPD meetings.

The first meeting of the EUROPNEUMO took place in 1993 and the first meeting of ISPPD was held in 1998. The two groups meet on a bi-annual basis.

☆Change History: July 2014: A Tomasz and R Sá-Leão updated the text and further readings to this entire article.

Pneumococcus as a Pathogen and as a Model Microbe for Molecular Biology

Pneumococcus is altogether an amazing cell. Tiny in size, simple in structure, frail in make-up, it possesses physiological functions of great variety, performs biochemical feats of extraordinary intricacy and, attacking man, sets up a stormy disease so often fatal that it must be reckoned as one of the foremost causes of human death

Benjamin White, 1938 in. The Biology of Pneumococcus

Streptococcus pneumoniae was first described in 1881 by Pasteur and Sternberg in independent observations. In the same decade, this Gram-positive pathogen with lancet-shaped cells which grow in most media in pairs or short chains of 'diplococci' was recognized as a major cause of infections that included pneumonia, meningitis, otitis media and endocarditis. *S. pneumoniae* routine identification is done through the alpha haemolysis surrounding colonies obtained on blood agar, negative reaction with catalase, susceptibility to optochin and solubility of the bacteria in bile salts. Most *S. pneumoniae* isolates are shielded by a polysaccharide capsule which hinders phagocytosis. Over 95 different capsules have been described to date and serologic typing (serotyping) remains one of the most frequently used methods for the characterization of pneumococcal isolates.

Since its discovery, this bacterium has been the subject of intensive studies as a cause of major and often life threatening human infections. While the primary aim of these studies was the control of pneumococcal disease, the same efforts have also led to seminal scientific discoveries in the laboratory which included the identification of the pneumococcal polysaccharide antigens as vaccines, the ability of capsular polysaccharides to induce antibodies, the discovery of bacterial gene transfer which led to the identification of the 'transforming principle' (later named DNA) as the genetic material (Avery et al, 1944). Efforts to degrade the capsular polysaccharide surrounding the pneumococcus have led to the first use of an 'enrichment culture'. The remarkable and rapid dissolution of pneumococci by bile led to the identification of the first bacterial autolytic enzyme. The pneumococcus was among the first pathogens in which the therapeutic efficacy of the newly discovered penicillin was tested. The role of the polysaccharide capsule providing resistance against phagocytosis was identified and studies on the rapid fluctuations in the pneumococcal capacity to take up DNA from the medium and undergo genetic change has led to the identification of the first bacterial quorum sensing factor (Tomasz, 1965).

Thus, efforts to understand and control pneumococcal disease went hand in hand with some of the fundamental discoveries of molecular biology. Interestingly, many of these phenomena first discovered in the in vitro world of the microbiology laboratory were subsequently identified as major factors driving the evolution of new pneumococcal lineages in the real life world of pneumococcal colonization, infection and disease.

The most promising – and ambitious – current efforts to understand the impact of antibiotics and vaccines on the pneumococcal colonization, infection and disease in humans are combining carefully designed epidemiological studies with the characterization of pneumococcal isolates by high resolution molecular techniques developed in the molecular biology laboratory.

Burden of Pneumococcal Disease

In the pre-antibiotic era, pneumococcal pneumonia was so common and fatal that it was termed as the 'old man's friend' and the 'captain of the men of death' by William Osler.

In the late 1990s, before the introduction of the first pneumococcal seven-valent conjugate vaccine in the US, data from the Center for Disease Control and Prevention estimated the annual frequency of pneumococcal infections as 3000 cases of meningitis, 50 000 cases of bacteremia, 500 000 cases of pneumonia, and 7 million cases of otitis media with an estimated mortality of about 40 000 deaths per year.

While no similar dependable estimates are available from the less developed countries in the world, evaluation of the impact of a nine-valent conjugate vaccine in one randomized control trial conducted in Africa clearly indicated that pneumococcal disease is a major contributor to the mortality of children in African countries.

In the Gambia, 77% (95%CI, 51-90%) efficacy against vaccine type invasive pneumococcal disease was found with a 50% (95% CI, 21-69%) efficacy against all types of invasive pneumococcal disease. Furthermore, a 16% (95%CI, 3-28%) decrease in all-cause mortality was found among vaccinated children. In South Africa, the efficacy of the nine-valent pneumococcal conjugate vaccine against invasive pneumococcal disease among HIV-negative children was 83% (95%CI, 39-97%) and corresponding figures were 65% (95%CI, 24-86%) among HIV-positive children.

A report in 2007 from the WHO estimated that 1.6 million people continue to die every year due to pneumococcal disease including 0.7-1 million children aged less than 5 years, the majority living in developing countries where the pneumococcal conjugate vaccine is not available. The burden of disease associated with the elderly in these countries remains to be defined.

In addition to young children and the elderly, individuals of all ages infected with HIV are at a substantial higher risk of serious pneumococcal infection. For example, the risk of pneumococcal pneumonia is 25-fold higher among HIV-infected people compared to HIV-uninfected people. The incidence of pneumococcal invasive disease among HIV-positive children is nine to 43 times higher than among HIV-negative children and the rates of IPD among HIV-positive adults are 6 to 343 times higher than among HIV-negative adults.

Pneumococcal Infection and Viral Disease

In the era of preparedness for an anticipated new influenza or bird flu pandemic the well-documented contribution of pneumococci in the mortality associated with flu becomes increasingly important.

Several lines of evidence have highlighted that secondary infections by pneumococci in patients with viral respiratory disease can have devastating consequences. Studies conducted during the 1918 influenza epidemic which is estimated to have led to at least 40–50 million deaths, demonstrated that an important fraction of the deaths took place 2 weeks after the onset of influenza symptoms suggesting that superinfection by a common bacterial respiratory pathogen had occurred. Direct evidence supporting the role of pneumococcal secondary infection leading to fatal pneumonia has been described.

In a double-blind, randomized, placebo-controlled trial of a nine-valent pneumococcal conjugate vaccine in South Africa, it was found that the vaccine prevented 31% of virus-associated pneumonia in hospitalized children, suggesting that an important fraction of virus-associated pneumonia among hospitalized children was attributable to bacterial co-infection which could be prevented by bacterial vaccines.

Experiments on modeling viral-bacterial infection in animals showed that if a mouse model was challenged with a non-lethal dose of influenza virus and approximately seven days later was challenged with pneumococcus, 100% mortality occurred. This effect was specific for viral infection preceding bacterial infection.

Altogether these data strongly suggest that pneumococcal vaccination could have a beneficial role in preventing influenza-associated mortality in the advent of a new influenza pandemic.

The Natural Reservoir of *S. pneumoniae*

Humans are not only the target of diseases caused by *S. pneumoniae* but are also the primary ecological reservoir of this bacterial pathogen - although anecdotic studies have found carriage of pneumococci by horses and other human-handled mammals, and isolation from wild deceased chimpanzees. Thus, interventions to combat pneumococcal disease such as the introduction of antibiotics or vaccines also impact on the human nasopharyngeal flora of pneumococci selecting for drug resistant lineages and strains with less common capsular types. In this sense, Man is also an evolutionary partner of this microbe and many - if not all - of the genetic events that allow these bacteria to borrow pieces of foreign DNA to remodel their penicillin sensitive enzymes, acquire mobile elements that confer antimicrobial resistance to different classes of antibiotics, or undergo capsular switches to evade the action of vaccines targeting the capsule most likely occur in pneumococcal populations that inhabit the human nasopharynx, more specifically, the nasopharynx of preschool age children. The latter, for reasons not fully understood, are the primary carriers of this bacterial species. For these reasons the day care centers in which preschool age children are now recruited in many of the countries of the developed world have become major foci of epidemiological studies of pneumococci.

Indeed, several studies have shown that children of preschool age are the major reservoir of pneumococci and by school time a spontaneous decrease in carriage (or, at least, in carriage density) occurs. The mechanism of extensive colonization in infancy and the loss of carriage with age are not well understood. It is also well established that in infancy, in the absence of multivalent pneumococcal conjugate vaccines, the most dominant capsular types colonizing the nasopharynx are typically of the serogroups 6, 9, 14, 19 and 23 in countries across the world. This commonality of serotypes colonizing the young host contrasts with the well documented and sometimes extensive differences in the serotypes of pneumococci that most frequently cause invasive disease in various parts of the world at a given time. The mechanism of geographic variation in serotype abundance and their change in time is not known.

An important source of problems contributing to the difficulties of interpretation of many aspects of pneumococcal epidemiology is the way pneumococcal colonization has been routinely assayed in the overwhelming majority of the studies conducted so far. In most studies, a single colony recovered on blood agar plates from the nasopharyngeal swabs is assumed to represent the entire colonizing flora. However, simultaneous carriage of multiple strains of pneumococci in the nasopharynx has been known for several decades and was documented in early studies conducted in the 1930s and 1940s which used mouse inoculation assays to detect the strains. As these methods were very labor-intensive and expensive they have been abandoned. More recent studies in which a number of colonies were picked from the primary blood agar plates and were characterized clearly showed that the nasopharyngeal flora is heterogeneous: it may be composed of more than one strain of pneumococci; some representing the majority, others - often present with lower frequencies - may be of completely different serotypes and molecular types (Table 1). Recent studies based on DNA-based technologies highly sensitive to detect multiple serotypes in carriage samples are being developed and shedding light on this phenomena (Valente et al., 2012). Certain pneumococcal serotypes such as serotypes 1 and 5 that can be recovered from disease sites but have seldom been seen in the nasopharynx may represent such minority residents in the nasopharyngeal flora. The same minority clones may be the source of the novel pneumococci emerging after the introduction of the conjugate pneumococcal vaccine.

Multiple pneumococcal carriage is apparently more abundant among populations with high pneumococcal carriage rates such as children from Papua New Guinea, Gambia or Australian Aborigines. Multiple carriage rates in the range of 20–30% have been reported among these populations. Among other children typical rates of multiple carriage have been in the range of 10–20%.

Table 1 Properties of multiple isolates obtained from nasopharyngeal samples containing two strains of *S. pneumoniae*.

Stages in Pneumococcal Pathogenesis: Virulence Factors and Host Defense

Virulence in pneumococci is multifactorial and involves complex and multiple interactions with the host. Well over 300 genes have been implicated in virulence in at least one animal model of pneumococcal infection. A genome wide screen – by signature tagged mutagenesis – of the reference strain TIGR4 for genes essential for lung infection in an animal model identified close to 400 genes. Individual putative virulence factors appear to play a variety of roles – both ‘aggressive’ as well as ‘defensive’ at various stages of pneumococcal infections. Some of the pneumococcal virulence factors are present in virtually all pneumococcal isolates such as the capsular polysaccharide, the major autolysin *LytA*, the intracellular toxin pneumolysin (Ply), and sortase A (SrtA). Other important virulence determinants such as the pilus gene also play important roles in virulence but these determinants seem to be associated with specific clones of pneumococci. Secreted DNAase appears to have a role in escaping the neutrophil extracellular traps (NETs) and pneumococcal resistance to the widely spread cationic antimicrobial peptides appears to involve incorporation of D-alanine esters into the pneumococcal cell wall teichoic acids.

Host factors ‘matching’ in numbers the virulence genes of the pneumococcus have also been identified using a variety of models. These factors cover a wide range of functions: pattern recognition elements that are components of the innate immune system as well as host defense factors more specific for the invading pneumococcus such as the scavenger receptor involved with lung defense or the generation of adaptive immunity directed primarily against the capsular polysaccharide.

Capsular polysaccharides. While *S. pneumoniae* isolates free of the capsule do exist the overwhelming majority of clinical strains express one capsular polysaccharide attached to the pneumococcal cell wall. Non-encapsulated strains, for instance, strains R6 or R36A which are most frequently used in laboratory studies on *S. pneumoniae* are completely avirulent in animal models of disease. The role of the capsular polysaccharide in pneumococcal virulence appears to be the inhibition of complement-mediated opsonophagocytosis by macrophages or polymorphonuclear leucocytes (PMN). Except for the capsular polysaccharide type 3, all the other polysaccharide capsules appear to be covalently linked to the pneumococcal cell wall.

Pneumococci have an enormous genetic repertoire to produce – potentially – as many as 95 chemically different polysaccharide chains. A unique feature of the structure of capsular loci is that type specific genes are flanked by common determinants, thus allowing for a relatively easy exchange of genetic determinants within this region of the pneumococcal chromosome. The frequent ‘capsular switch’ that can appear spontaneously or driven by vaccine pressure among clinical isolates appears to be the consequence of a relatively easy genetic change at the capsular loci. In such cases, isolates that share common genetic backgrounds (defined by multilocus sequence type or pulsed-field gel electrophoresis profile) appear to differ only in the type of capsule at their surface. Whole genome sequencing, however, has revealed other more or less subtle changes in addition to the capsular operon.

Cell walls in virulence. The unique choline component of the wall and membrane teichoic acid appears to perform multiple roles both in the physiology of the pneumococcus and also as an interactive component with the host. The species of *S. pneumoniae* is unique in that it requires as an essential nutrient choline for growth. Recently, pneumococcal strains have been isolated in which this auxotrophic requirement for choline is lost. In one of these isolates point mutations in one of the choline utilization genes – *tacF* – have been identified as the mechanism responsible for the choline independent growth. TacF, a teichoic acid flippase was proposed to catalyze the transfer of teichoic acid chains across the pneumococcal plasma membrane. A second choline independent strain was recovered from a heterologous genetic cross in which *S. oralis*, a bacterial species that contains choline in its teichoic acid but does not require choline for growth, served as DNA donor and the recipient was the R6 strain of *S. pneumoniae*. The mechanism of choline independence in this strain called R6Cho⁻ appears to be different from the mechanism identified in the other choline independent mutants.

Recent studies have shown that pneumococcal constructs capable of growing without choline and expressing the capsular polysaccharide type 2 on their surface have severely reduced virulence potential in several animal models of pneumococcal disease and are also inhibited from colonizing the nasal epithelium of mice. The mechanism of this striking impact of the teichoic acid choline units on pneumococcal virulence is not understood at the present time.

Pneumococcal cell wall components were shown to induce the production of preinflammatory cytokines both in the murine intraperitoneal models as well as in the rat and rabbit models of meningeal disease. Structural features of the peptidoglycan involved with the recognition by the innate immunity system have been identified in the *Drosophila* model.

At least two pneumococcal cell wall modifying enzymes: PGDA, a peptidoglycan glucosamine deacetylase and PCE, a phosphoryl choline esterase, were shown to play roles in virulence as indicated by the impact of inactivation of the corresponding genetic determinant on virulence.

Regulation of Virulence

The expression of capsular polysaccharides appears to be regulated: contact with epithelial cells was shown to cause suppression in the amounts of capsule which can subsequently increase once the bacteria have reached the blood stream.

Different modalities of growth. Recent studies have shown that pneumococci can grow in two different modalities: as planktonic cells typical of bacteremic infections and as biofilms typical of colonization. Different sets of genetic determinants are expressed matching these two different growth styles of pneumococci.

Opaque versus transparent phenotype. In 1994, Weiser et al described that pneumococci could undergo phase variation, that is changes in properties of the cell surface could lead to two different colony phenotypes: opaque and transparent. Spontaneous, reversible variation between the two colony phenotypes with a frequency ranging from 10^{-3} to 10^{-6} per generation has been described. This frequency appears to be independent of in vitro growth conditions.

The same authors showed that the opaque phenotype was associated with increase amounts of capsular polysaccharide and pneumococcal surface protein A (PspA) while transparent variants were associated with increased amounts of choline binding protein A (CbpA) and autolysin A (LytA). Opaque colonies were described as dome shaped and large contrasting with transparent colonies which were umbilicated, suffered quicker autolysis and had a higher efficiency of natural transformation. Cultures obtained from opaque colonies had decreased binding of serum C-reactive protein, decreased opsonophagocytosis and increased virulence in systemic infections. By contrast, transparent colonies had increased adherence, and colonized more efficiently in an animal model of carriage.

More recently, DNA microarray strategies have identified an additional number of genes, which appear to have differential regulation between isogenic pairs of strains displaying opacity or transparent phenotypes. In particular, the transparent phenotype was associated with increased production of neuraminidase (NanA).

Studies on the fatty acid composition of pairs of opaque and transparent colonies found a lower degree of unsaturated fatty acids in the opaque variants.

A single large study has attempted to examine the prediction that opaque variants are associated with increased pathogenesis by looking at the colony phenotypes displayed by a large collection of invasive disease isolates with a low number of in vitro passages. This collection of 304 isolates included representatives of 10 serotypes displaying genetically diverse backgrounds (Serrano et al., 2006). The authors confirmed that the opaque phenotype dominated among invasive disease isolates but also noted a previously unreported association between serotype and colony phenotype. This observation led them to suggest that the association between the opaque phenotype with particular serotypes might contribute in part to explain observed differences in the invasive disease potential of certain serotypes.

Contribution of Genotype and Serotype to the 'Invasive Disease Potential'

The introduction of molecular typing techniques for the characterization of *S. pneumoniae* recovered from disease and from colonization sites combined with extensive epidemiological studies has initiated efforts to better define the contribution of serotype versus molecular type to the 'invasive' potential of a pneumococcal strain. The frequent representation of the so-called pediatric serotypes (primarily 6B, 14, 19F and 23F) in the nasopharyngeal flora of children clearly provides an increased opportunity for strains expressing these serotypes to invade during periods of decreased host defense. Thus, assignment of a true 'invasive disease potential' to a strain must take into account the odds ratios expressing the frequency of recovering the particular strain from colonization versus infection sites.

The relative contribution of serotype versus genotype to the invasive disease potential is a currently unsettled issue. Although it is relatively consensual that the capsular type expressed is extremely important for the disease potential of a particular strain, there are studies suggesting that the genetic background of that strain is also important, which, after all, is in agreement with the finding of several genetic determinants essential for full virulence of pneumococci.

A further potential problem contributing to the difficulties of interpretation of these empirical estimates of invasive disease potential of serotypes and clones of pneumococci is the way pneumococcal colonization has been traditionally studied ignoring multiple colonization (discussed above).

The relative contribution of the host versus the pathogen for the occurrence of pneumococcal infection is debatable but clearly the host plays a very important role. Recent studies have started to identify genetic polymorphisms in determinants implicated in the host immune response including some that are associated with susceptibility to invasive pneumococcal disease and others that confer a protective effect to it.

Human Intervention

There have been at least three important interventions by man that radically altered the *in vivo* landscape and epidemiology of *Streptococcus pneumoniae*: (i) the introduction of antibiotics into therapeutic practice; (ii) the introduction of the conjugate anti-pneumococcal vaccine and (iii) the massive emergence of day care centers in the developed part of the world.

The introduction of antibiotics did not change the incidence of pneumococcal infections; it contributed significantly to the control and outcome of pneumococcal disease but has also led to the emergence of antibiotic resistant strains.

The introduction of multivalent conjugate anti-pneumococcal vaccines in several countries worldwide is having a major impact on the incidence of invasive pneumococcal disease. Although these vaccines prevent colonization by capsular types targeted by them, the rate of pneumococcal carriage does not decrease. Furthermore, as these vaccines target serotypes frequently associated with antibiotic resistance, the frequency of antibiotic resistant strains among colonizing pneumococci has initially decreased (following introduction of these vaccines), but is now bouncing back due to expansion of pneumococcal non-vaccine capsular serotypes also resistant to antibiotics (Simões et al, 2011).

The institution of day care has emerged as a unique epidemiological entity in which many children of preschool age are cohorted. The high carriage rate of respiratory pathogens, immunological status and typical child behavior, together with the frequent occurrence of viral respiratory diseases and the extensive and often imprudent use of antimicrobial agents among this age group are the most likely reasons why attendance at day care centers has become a risk factor for both carriage and infection by antibiotic resistant strains of pneumococci.

Antibiotic Resistance and Insights Provided by Molecular Typing

The first penicillin resistant strain of *S. pneumoniae* that appeared in the clinical environment and invoked comments in the infectious diseases literature was the strain isolated from the throat of a healthy child in the mid 1960's in a remote village, Agunganak in Papua New Guinea. Although initially the possibility of geographic spread of the penicillin resistant pneumococcus was judged remote, this prediction was soon contradicted by the massive outbreak of pneumococcal disease in South African hospitals in 1977, which was caused by multidrug resistant strains of this bacterium. Between the early 1980s and the late 1990s reports on the detection and increase both in frequency and in antibiotic resistance level of drug resistant strains of *S. pneumoniae* have appeared in increasing numbers and the antibiotic resistant pneumococcus has become a global phenomenon that began to make effective chemotherapy sometimes problematic.

Global Spread of a few Pandemic Clones of Penicillin Resistant Pneumococci

Introduction of pneumococcal typing techniques such as pulsed-field gel electrophoresis (PFGE) or multilocus sequence typing (MLST) has clearly shown that among the very large number of lineages of resistant pneumococci a handful of highly epidemic clones emerged and achieved massive and often pandemic spread. The most outstanding of these is Spain^{23F} ST81 originally called the 'Spanish/USA clone' (now called 'PMEN-1' clone – for Pneumococcal Molecular Epidemiology Network 1) usually expressing serotype 23F and carrying resistance to penicillin, tetracycline and chloramphenicol and often to erythromycin and sulfamethoxazole-trimethoprim.

An apparent intercontinental transfer of this clone from Southern Europe to the United States was demonstrated. This clone was subsequently identified in numerous national and international surveillance studies, both as a powerful colonizer and also as a strain capable of causing the entire spectrum of pneumococcal diseases among both adults and children.

Similar importation of a multidrug resistant pneumococcal clone, the penicillin resistant clone Spain^{6B} ST90 (now called 'PMEN-2' clone) presumably from Southern Europe to Iceland was demonstrated in the early 1990s. This so-called 'Icelandic' clone expressing serotype 6B and resistance to penicillin, tetracycline, chloramphenicol, erythromycin, sulfamethoxazole-trimethoprim and occasionally to third generation cephalosporins as well, quickly spread in Iceland and within three years of its detection was shown to be responsible for close to 20% of all pneumococcal disease in that country.

A third genetic lineage France^{9V} ST156 originally referred to as the 'French/Spanish' clone carries resistance to penicillin and tetracycline and occasionally to sulfamethoxazole-trimethoprim and typically exists in two capsular serotypes: 9V or 14. This clone (PMEN-3) was shown to have spread in Europe, Latin America, USA, Canada and Asian countries.

The introduction and widespread use of molecular typing techniques has led to the establishment of an international depository and 'clearing' house for characterized *S. pneumoniae* clones the so called Pneumococcal Molecular Epidemiology Network (PMEN, for more information visit www.sph.emory.edu/PMEN/). This platform has become also useful in providing a uniform set of rules to name new clonal lineages, register both their molecular as well as epidemiological characteristics, serotypes, isolation dates and sites and clinical sources as well.

Despite the fact that penicillin resistant strains have been isolated from countries all over the world, their incidence varies widely from country to country and from one geographic site to another.

The impact of antibiotic resistance on chemotherapy varies with the particular infection. Even low-level resistance to antibiotics requires change in chemotherapy in meningitis because of the low penetration of the cerebral spinal fluid by this class of antibiotics and because of the need for bactericidal concentrations. On the other hand, penicillin therapy was shown to remain effective in pneumococcal pneumonia caused by penicillin resistant strains with MIC values as high as 1–2 µg ml⁻¹.

Penicillin Resistance: Genes and Phenotypes

The mechanism of penicillin resistance in pneumococcal clinical isolates is based on the remodeling of several of the genetic determinants – *pbp* genes that encode for proteins PBPs (penicillin binding proteins) that catalyze various stages in the pneumococcal cell wall synthesis. The process of remodeling involves recombinational events with fragments of *pbp* genes imported from heterologous species most often from *S. mitis*. These 'mosaic' *pbp* genes produce PBPs with decreased affinity for penicillin which is the ultimate basis of the increased penicillin MIC values.

Examination of the cell wall chemical structure in penicillin resistant clinical isolates showed additional profound abnormalities in these bacteria, specifically the increased representation of branched mucopeptide components in their cell wall peptidoglycan. A genetic follow-up of these studies identified the new determinants *murM* and *murN*, responsible for the biosynthesis and attachment of the two amino acid components that form the mucopeptide branches. The *murM* and *murN* genes of resistant strains showed clear evidence of mosaicism, indicating the presence of DNA sequences of heterologous origin. Most interestingly, inactivation of *murM* caused a complete loss of penicillin resistance which could be recovered in appropriate complementation experiments. A detailed biochemical mechanism of the synthesis of pneumococcal mucopeptides and the mode of action of MurM and MurN proteins was recently described.

The critical nature of cell wall chemistry for the penicillin resistant phenotype was further documented by the recent identification of yet another cell wall modifying enzyme: a muramic acid O-acetylase. Inactivation of the structural gene named *adr* caused loss of penicillin MIC value, similarly to the case of strains in which MurM was inactivated.

It seems that genetic determinants in addition to the mosaic *pbp* genes producing the low affinity penicillin targets are also essential for optimizing the resistant phenotype. This scenario is reminiscent of the mechanism identified in methicillin resistant *Staphylococcus aureus*, in which high level resistance requires not only the central resistance determinant *mecA*, but a number of additional 'auxiliary determinants' as well in the genetic background of the bacteria.

Genetic Diversity Among Penicillin Resistant and Penicillin Susceptible Pneumococci Causing Invasive Disease

Several studies have compared the genotypes of penicillin resistant (MIC higher than 1 µg ml⁻¹) versus penicillin susceptible isolates of pneumococci expressing the same serotypes and recovered from invasive disease. Studies with strains isolated from children in South American countries are illustrative of the common findings of such studies. The major and striking difference among the resistant and susceptible isolates was the relative genetic homogeneity of most resistant isolates, over 80% of which were shown to belong to one of two pandemic penicillin resistant clones: Spain^{23F}-ST81 and/or France^{9V/14} ST156 - Figure 1. In contrast, penicillin susceptible isolates expressing the same serotypes and recovered from similar disease sites showed great genetic diversity – Figure 2. A similar – inverse – relationship between genetic diversity and penicillin MIC value has already been described in other epidemiological studies. These observations may reflect the expensive 'fitness' cost associated with the mechanism of pneumococcal penicillin resistance which may only be compatible with a limited number of genetic backgrounds available in this bacterial species.

Figure 1 Pie chart showing the isolation percentages in Latin America of two penicillin resistant pandemic clones versus all other clones from among 172 penicillin resistant invasive isolates. Note that the two clone types (A and B) are responsible for ~81% of all pneumococcal infections. Clone A (serotype 23F) refers to the Spain^{23F} ST81 clone and clone B refers to the France^{9V} ST156 clone. Adapted from Tomasz et al. 1998 *Microb Drug Resist* 4:195–207.

Figure 2 Pie charts (from left to right) showing the large number of different MLST types (ST's) for each of the three most prevalent capsular types (serotypes) 14, 23F and 6B that were associated with clinically invasive penicillin-sensitive pneumococcal disease in Latin America. Figure taken from Zemlickova et al. 2005. *Microb Drug Resist* 11:195–204.

Impact of the Seven-Valent Pneumococcal Conjugate Vaccine on Pneumococcal Disease and Carriage

In 2000, a seven-valent pneumococcal conjugate vaccine (PCV7 targeting serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F) was licensed in the US and soon after in many other countries worldwide. The vaccine was intended for children younger than two years old. This vaccine was formulated to target the serotypes that cover over 80% of the cases of invasive pneumococcal disease among children younger than 5 years old in the US. Expected coverage rates in other countries, particularly in developing countries, are lower.

Following introduction of PCV7 in the US, a reduction in incidence of invasive pneumococcal disease (IPD) occurred not only among young children but also in all other age groups due to a substantial indirect herd effect. In particular, a sharp decrease in IPD caused by vaccine types was observed which was accompanied by a modest increase in IPD caused by non-vaccine types. By 2003 the total incidence of IPD among children <5 years of age had declined 75% from 96.7 cases per 100 000 population to 23.9 and among those aged 65 or older a 29% decline was observed from 60.1 cases per 100 000 population to 41.7 cases.

The observed indirect effect of the vaccine is best explained taking into account that the vaccine decreases carriage of vaccine-types among vaccinees and these are the major reservoirs of pneumococci. By vaccinating young children, transmission of vaccine types has decreased substantially. An earlier study from Israel had demonstrated an indirect beneficial effect of PCV7 among children too young to be vaccinated whose siblings had received PCV7. The same studies showed that pneumococcal colonization levels remain stable after vaccination due to a serotype replacement effect that results in the nasopharynx becoming mostly colonized by non-vaccine types.

An added bonus of the vaccine relies on the fact that most antimicrobial-resistant pneumococci isolated worldwide including those non-susceptible to penicillin, and/or resistant to macrolides, or multidrug-resistant express mostly serotypes targeted by PCV7 (i.e. 6B, 9V, 14, 19F, and 23F). In agreement with these observations, a decline in antimicrobial-resistant pneumococci has been observed in the US among isolates causing invasive pneumococcal disease. However, recent reports from the US and elsewhere found that among colonizing isolates as well as those causing respiratory tract infections, levels of antimicrobial resistance among non-vaccine types are increasing suggesting that the impact of PCV7 on antimicrobial resistance may be short lived.

The phenomenon of serotype replacement and the short-lived effect of PCV7 on antimicrobial resistance are also beginning to be noticed in other countries that are using PCV7. For example, a study on the impact of PCV7 on pneumococci carried by Portuguese day-care center attendees observed that serotype replacement has occurred among attendees regardless of their vaccination status

Figure 3 Bar charts showing the number of clinical isolates recovered of each pneumococcal capsule type (serotype) before introduction (2001) of PCV7 (top graph) and after vaccine introduction (2006) in Portugal (bottom graph). All capsular types targeted by the vaccine dropped in recovery and most non-vaccine types increased in abundance. Adapted from Sá-Leão et al., 2008.

(57% of the children had been vaccinated) (Figure 3). In other words, unvaccinated children were benefiting from being in contact with vaccinated children. Interestingly, rates of antibiotic resistance remained unchanged due to a balance between reduction of vaccine types and an increase of antimicrobial resistance among non-vaccine types.

Novel vaccines with greater valency - 10-valent (PCV7 serotypes plus 1, 5, 7F) and 13-valent (PCV10 serotypes plus 3, 6A, and 19A) have now been introduced in the market. These expanded valency vaccines include serotypes which are major causes of IPD in developing countries such as serotypes 1 and 5. The 13-valent conjugate vaccine also targets serotype 19A which, it has become in the last decade an important cause of IPD in some countries such as the US and is often multidrug resistant.

Universal protein vaccines – which should have broad coverage and low price - are currently in different stages of development.

Day-Care Center Studies

Day-care centers, have become increasingly frequent in the last decades in the developed world and their impact on infectious diseases has been discussed. In particular, several studies have focused on pneumococcal carriage among day care center attendees. Molecular epidemiological studies have shown that these ‘novel’ institutions play a crucial role in the transmission and amplification of pneumococcal lineages. Furthermore, marked differences in pneumococcal carriage rates across communities have been explained by differences in the proportion of children who attend day-care centers in those communities.

Perhaps one of the largest surveillance initiatives of pneumococcal carriage among day-care center attendees has been the one conducted in Lisbon and Oeiras, Portugal. The project began in 1996 and through the years, an ever-growing collection of isolates has been obtained. As of February 2014, over 14 000 nasopharyngeal samples have been collected, resulting in the isolation of over 9500 pneumococci. Approximately 40% of the isolates were resistant to at least one commonly used antimicrobial agent. All drug-resistant isolates have been characterized by capsular type and antimicrobial susceptibility pattern, and several by molecular typing either by pulsed-field gel electrophoresis (PFGE) and/or multilocus sequence typing (MLST). Over 40% of the fully susceptible pneumococci have also been characterized by the same combination of techniques (Sá-Leão and de Lencastre personal

communication). These and other studies have provided insights on the natural biology and population structure of pneumococci, on the dynamics of the carrier state, and on the properties of day-care centers as epidemiological entities.

It was observed, for example, that day-care centers (DCC's) are autonomous epidemiological units, which, at a given time, differ from each other in the pneumococcal population circulating among its attendees, even if the units are geographically close.

A longitudinal study showed that introduction of novel pneumococcal lineages occurred all year long in the DCCs and the fittest lineages were transmitted among attendees for several months resulting in their amplification and providing ample opportunities for their spread in the open community as well.

Portuguese DCC attendees were found to be frequently colonized by pneumococci: in winter months an average of 65% of children were found to be carriers and virtually all children (98%) carried pneumococci at least once during a one-year longitudinal study. It was also shown that the nasopharyngeal flora of DCC attendees was a reservoir of internationally disseminated drug resistant lineages capable of causing the entire spectrum of pneumococcal diseases, such as the successful clones Spain^{23F} ST81, Spain^{6B} ST9, and France^{9V} ST156.

Genetic Exchange in Vivo

Several of the intriguing phenomena first observed during studies of pneumococci in the microbiology laboratory also play important roles in the in vivo environment of this bacterium. DNA mediated genetic transformation appears to be a major mechanism for acquiring antibiotic resistance genes and also for switching capsular type – as observed in epidemiological studies. The release of DNA through the activity of autolytic enzymes also appears to play an important role in the in vivo evolution of pneumococcal lineages.

Competence

Competence is a transitory state in which bacterial cells are able to take up exogenous DNA. This process may lead to genetic transformation if during the competent state there is exogenous DNA available in the environment – particularly if the DNA has high degree of homology to the DNA of the competent recipient cell. Nevertheless, heterologous DNA from other streptococcal species can also serve as 'donor' in recombinational events.

Pneumococcal competence has been studied for over four decades. However, it was during the last decade that major breakthroughs have been made in the elucidation of the molecular mechanisms leading to competence, the genes implicated in the competence regulon, and its role in pneumococci.

As of today most studies in this area are done based on a few well-characterized laboratory strains. Nonetheless, competence appears to be widely disseminated in pneumococci: a study on the distribution of two competence genes among a diverse collection of 214 clinical isolates found that both genes were ubiquitous in the collection.

The competent state is controlled by the early *com* genes *comABCDEWX*. Competence is triggered by accumulating exogenous levels of the 17 amino acids long pheromone CSP (competent stimulating peptide). The pre-CSP is 24 aa long encoded by *comC*, which is cleaved to CSP during export across the cytoplasmic membrane. This process uses a dedicated secretion apparatus coded by *comAB*. Competence is triggered by CSP stimulation of its receptor *comD*, a membrane-bound histidine kinase which autophosphorylates and transphosphorylates its cognate response regulator *comE*. *ComE* binds to a specific site in the DNA activating the early competence genes, including *comABCDE*, leading to further accumulation of CSP, and *comX*. This latter gene encodes a sigma-X factor which activates the transcription of the late competent genes.

Two transcriptomic studies using DNA microarrays have identified over one hundred genes induced by CSP. Ninety-one genes were common to both studies and included 17 early *com* genes and 60 late *com* genes. Of significant interest, it was shown that only 22 genes of the *com* regulon are required for transformation suggesting that the role of competence extends well beyond genetic transformation.

In the past decade it was discovered that competent cells have the capacity to trigger the lysis of genetically identical as well as non-identical non-competent cells. This phenomenon of 'fratricide' predation has been termed allolysis. A bacteriocin system named *CibABC* (competence induced bacteriocin) consisting of a two-peptide *CibAB* bacteriocin and its immunity factor *CibC* has been identified. It was shown that *CibAB* is absolutely required for allolysis but cannot promote lysis per se. Gene *cibC*, encodes a 65 aa peptide with two predicted transmembrane segment. Evidence suggests that cell-to-cell contact is necessary for allolysis to occur. It was proposed that *CibAB* may insert into the membrane of noncompetent cells (which lack *CibC*) and deplete them of energy. Cell lysis of noncompetent cells would then occur as a consequence of the action of three amidases - *LytA*, *LytC*, and *CbpD*.

The observation that allolysis occurs during the transient state of competence (*cibABC*, *lytA* and *cbpD* are late genes of the *com* regulon) is probably intimately related to its biological significance. Current hypotheses on the contribution of allolysis to the biology of pneumococci include not only DNA release for genetic transformation but also a role in colonization and/or virulence, competition between strains and release of virulence factors. The elucidation of the mechanism of competence has recently seen several important advances several of which have been reviewed recently (Johnston et al, 2014).

Bacteriophages of Pneumococci

Pneumococcal bacteriophages of the lytic and temperate types were first described in 1970s. Subsequent work on pneumococcal phages found that the lytic enzymes of many of them shared a high identity (at the protein and DNA level) to the major pneumococcal autolysin (*LytA*).

The incidence of prophages among a large collection of pneumococcal clinical isolates was high - 76% - and multiple carriage was frequent. The initial observations were based on the fact that multiple bands of SmaI-digested total DNA separated by PFGE hybridized with a *lytA* probe. Further assays on a subset sample of 17 isolates showed that the majority of the isolates tested (11 of 17) contained functional prophages that entered the lytic cycle following mitomycin induction. Some PFGE subtypes of SmaI-digested total DNA could be explained by changes in the number and chromosomal localization of prophages suggesting that prophage carriage could be used as a molecular epidemiological marker (Ramirez et al., 1999).

In recent years, the use of pneumococcal phage lytic enzymes as anti-infective agents has been explored. It was shown that a purified pneumococcal bacteriophage lytic enzyme (Pal) was able to rapidly kill pneumococci of common serotypes including highly penicillin-resistant strains. In an animal model of colonization, pneumococci were eradicated without disturbing the normal flora. Following these initial studies, the therapeutic use of bacteriophage enzymes has been tested with success in different animal models of disease (bacteremia, endocarditis, and otitis media).

More recently, the pneumococcal LytA autolysin was found to be a potent therapeutic agent in experimental peritonitis-sepsis caused by highly beta-lactam-resistant *Streptococcus pneumoniae*.

Genome Sequencing

The first three pneumococcal genomes sequenced were TIGR4 (serotype 4 invasive disease isolate from Norway), R6 (avirulent, non-capsulated derivative of the serotype 2 strain D39), and G54 (serotype 19F derivative of a serotype 15 clone from Spain). All were published in 2001. Since then an increasing number of strains have been sequenced as novel and affordable sequencing technologies and more powerful bioinformatic tools became available, lowering dramatically the costs and time needed for such projects. As of 2014, high quality sequence information is available for numerous *S. pneumoniae* isolates. Full genome sequencing was used to characterize 240 isolates of the PMEN-1 clone – collected from several countries over an extended time period (Croucher et al., 2011). Other genome sequencing projects are ongoing. Among the genome sequences available are representatives of the most successful pandemic drug-resistant clones as well as representatives of susceptible strains that are frequent causes of invasive pneumococcal disease in countries of the developing world. In addition, the capsular operons of all capsular types described to date have been sequenced.

Pan-Genome of *S. pneumoniae*

The size of the pneumococcal genome depends on the strain analyzed. Among strains sequenced so far it is generally in the range of 2.0–2.2 Mb. Evidence obtained up to now supports the hypothesis that pneumococci (as other highly recombinogenic bacteria) contain a supragenome that is much larger than the genome of any individual strain. Each pneumococcus genome contains a core set of genes (common to all pneumococci) and a non-core set of genes that are part of a large pool of genes.

Comparative genomic analyses published so far, used the combined analyses of the genome sequences of numerous strains, to estimate the number of orthologous clusters in the pneumococcal supragenome based on a finite-supragenome model. The model predicted that the pneumococcal supragenome should contain approximately 5100 orthologous clusters of which 27% are core, 41% are unique, and the remaining 32% are distributed (i.e., present in more than one strain but not common to all).

Pneumococcal Cell Wall: Composition, Structure and Mechanisms of Replication During Cell Division

The cell wall is composed in approximately equal proportions of a peptidoglycan and a teichoic acid of unusual chemical composition, the components of which include galactosamine phosphate, 2,4,6-trideoxy-2,4-diaminohexose, ribitol phosphate and phosphocholine. A membrane teichoic acid of identical primary structure is also present at the cell surface.

High resolution chemical analysis of the peptidoglycan performed on many clinical isolates demonstrated that the composition of the pneumococcal peptidoglycan was specific for the species. The muropeptide units of the peptidoglycan of pneumococci are either directly crosslinked to one another or are crosslinked via short dipeptide branches composed of either seryl alanine or alanyl alanine units which are attached to the free amino group of the stempeptide lysine residues. While direct crosslinks are the dominant mode of crosslinking in penicillin susceptible pneumococci, the branched peptides become the prominent mode of crosslinking in penicillin resistant strains.

Genetic determinants of the dipeptide branches have been acquired by pneumococci from an as yet unidentified extra species source. The genetic determinants *murM* and *murN* are essential for the expression of high level penicillin resistance.

The choline residues of the teichoic acid polymers were shown to perform critical and multiple physiological functions in *S. pneumoniae* and most recent studies also identified choline residues as major modulators of pneumococcal virulence in animal models of pneumococcal disease. The presence of choline residues was shown to be essential for a wide range of physiological phenomena such as separation of daughter cells at the end of cell division (LytB), sensitivity of pneumococci and pneumococcal cell walls to degradation by the pneumococcal autolysin (LytA); choline residues were shown to be essential for genetic transformation and the cell wall choline units were shown to serve as non-covalent attachment sites for a group of proteins, the so-called choline binding proteins, which serve multiple functions in the interaction of pneumococci with their eukaryotic hosts. The choline residues are also sites for the attachment of the C-reactive protein and for the large family of myeloma proteins.

Fine Structure of Cell Wall

The shape and size of microbial cells is imprinted in their cell walls which – in the case of *S. pneumoniae* – resembles an American ‘football’ with diameters of 1.0 – 1.5 micrometer from tip to tip and with a ‘waistline’ of 0.5 – 0.8 micrometer. The cell wall of *S. pneumoniae* appears in electron microscopic thin sections as a tri-laminar layer directly underneath the somewhat amorphous polysaccharide capsule.

Fine structure studies were done on a ‘rough’ (non-encapsulated) *S. pneumoniae* strain R6 which is a derivative of strain R36A. The overwhelming majority of laboratory studies that have been done on pneumococci over the past several decades all used either R36A, R6 or some simple mutant derivatives of these two strains. R36A was derived from strain D39 a clinical isolate expressing a serotype 2 capsular polysaccharide on its surface. R36A was selected after 36 serial passages of D39 in medium containing anti-capsular type II antibody. Strain R36A was shown to carry a 7510 base pair deletion involving five of the genetic determinants of the capsular type II genetic locus. The fully sequenced strain R6 is not isogenic with R36A: R6, unlike its ‘parent’ strain, carries an inactivating point mutation in the *dlt* gene and it also has a mucopeptide composition in which branched peptides typical of penicillin resistant isolates are frequent.

Replication During Cell Division

Similarly to the case of other streptococci, the pneumococcal surface is inherited in a conservative fashion during growth: old hemispheres of the cell surface assembled during the previous cell division are passed on intact to the daughter cells in each subsequent cell generation (Figure 4(a)).

The various polymeric components of the pneumococcal cell wall – the peptidoglycan, teichoic acid and capsular polysaccharide chains – all appear to enter the pneumococcal surface at a single centrally located growth zone. The wall teichoic acid chains are attached by covalent bonds to the peptidoglycan – presumably to the muramic acid C-6 hydroxyl residues which are also the attachment sites for the capsular polysaccharide chains and the recently discovered O-acetyl groups as well. The enzymes catalyzing these three types of reactions competing for the same peptidoglycan attachment sites are not known at the present time, neither is the physiological control of these reactions well understood.

Replication of the cell wall seems to occur through the carefully coordinated functioning of two synthetic systems: one that appears to catalyze a peripheral cell wall synthesis (see P in Figure 4(b)), and a second one which catalyzes septal growth of the cell wall (see S in Figure 4(b)). In a newly born cell the future site of cell division is indicated by a ‘raised cell wall band’ located at the perfect center of the coccoid shaped cell. The next step in cell division is an apparent splitting of the raised cell wall band into two ring-like structures which proceed to ‘move’ in a symmetrical fashion to the left and to the right of their initial position. Thus, as cell division progresses, the distance between the two rings increases (see P1, P2, P3 in Figure 4(b)) In parallel with this movement is the activity of the second – septally located – cell wall synthetic system which produces cell wall along the newly developing septum (see S1, S2, S3 in Figure 4(b)).

Studies by Morlot and colleagues indicate that the three bifunctional PBPs of pneumococci (PBP1A, PBP1B and PBP2A) as well as the two monofunctional penicillin binding proteins (PBP2B and PBP2X) are all colocalized to the center of the newly born pneumococcus and seem to remain there during the entire course of cell division. The localization of PBP3, a D-D-carboxypeptidase

Figure 4 4(a) Symmetrical movement of the cell surface during cell division of *S. pneumoniae*. Scanning electron micrograph of a chain forming pneumococcus shows cells in different stages of cell division. In the cell at the beginning of a division cycle the ‘raised cell wall band’ is shown just after separation to two ring-like structures catalyzed by enzymes participating in the peripheral cell wall synthesis (P1). Also shown is the beginning of septal wall synthesis (S1). During subsequent stages the distance between the two ring-like structures associated with peripheral wall synthesis (P2 and P3) increases gradually and so does the advance of the septal wall synthesis ring (S2 and S3). 4(b). Conservation of ‘old’ hemispheres of the cell wall and insertion of ‘new’ wall material in the vicinity of the new cellular septum.

seems to be unique in that PBP3 is present along the entire pneumococcal surface except the septal zone suggesting an abundance of donor muropeptides available at the site of active cell wall growth. A model to explain the coordination of septal versus peripheral cell wall growth has been proposed recently. The exact functioning and localization of other cell division related proteins possibly involved with cell division such as FtsA, the gene products of DivIVA and the newly described putative murein hydrolase PcsB is not clear at the present time.

Postscript

Writing an 'Encyclopedia' chapter on the *Pneumococcus* is a risky undertaking in the era of Pubmed and Google search: highly specific and detailed information fitting a reader's particular curiosity is instantly available upon pushing a few buttons on the computer. Also, the number of contributors and contributions to the microbiology of *Streptococcus pneumoniae* has increased substantially since the last edition of the Encyclopedia in the Year 2000. A Pubmed search of all papers with *S. pneumoniae* in their titles and/or abstracts published between January 2000 and January 2014 identified more than 15 000 publications with topics about equally divided between pneumococcal disease, epidemiology and drug resistance plus a number of papers on clinical trials. Even a comprehensive listing of these is clearly impossible.

With these caveats in mind, we shall provide the reader with an admittedly subjective sampling of the more recent activities and publications of the field, a kind of updated 'subject index with a narrative'. Using this treatise the interested reader may then launch his/her more detailed search of the literature.

Introduction

Streptomyces spp. are Gram-positive bacteria that typically colonize terrestrial and marine soils as free-living saprophytes. In addition, some species also colonize the rhizosphere of plant roots and even plant tissues. They have evolved complex morphological and physiological responses enabling them to adapt to large changes in their environments, for example adjusting to climatic variation or competition from other organisms inhabiting the same niche. In a similar manner to a filamentous fungus, they colonize the particulate environment of the soil by growing branching multigenomic hyphae that form a ramifying network in order to exploit a localized nutrient source. As saprophytes, they are responsible for the breakdown of complex biological polymers and, consequently, for carbon and nitrogen turnover. Being non-motile, they achieve dispersal by means of unigenomic spores borne on specialized non-feeding aerial hyphae (Figure 1). The latter grow out of the semi-aqueous environment inhabited by the feeding vegetative hyphae and ultimately undergo multiple coordinated cell division, generating chains of spores. The spores can then be dispersed by physical agents or the activities of motile animals inhabiting the same niche. The morphological differentiation leading to sporulation is fuelled by cannibalization of parts of the vegetative mycelium, while other parts exhibit physiological differentiation, leading to the synthesis of an elaborate array of secondary metabolites. These complex organic molecules are a significant reason why streptomycetes have achieved their status of industrial microorganisms of major importance. The streptomycetes produce an unparalleled diversity of bioactive secondary metabolites that have been exploited in medicine and agriculture as antibiotics, anti-cancer agents, immunosuppressants and pesticides.

These fascinating attributes have stimulated intensive research worldwide. Moreover, they are not only model systems to investigate microbial differentiation, but are also members of the same taxonomic order (Actinomycetales) as the causative agents of tuberculosis, leprosy and diphtheria (*Mycobacterium tuberculosis*, *M. leprae* and *Corynebacterium diphtheriae*, respectively). Investigating the biology of experimentally more tractable *Streptomyces* can inform critical aspects of the biology of these pathogens. This article reviews many of the fascinating and novel features of streptomycete biology, with particular focus on *Streptomyces coelicolor*. This is considered by many as the model species for which we have a profound although by no means complete understanding, helped in recent years by researchers having access to its annotated genome sequence. Researchers were originally attracted to this species because of its ability to synthesise a striking pigment, later shown to be a mixture of the blue antibiotic actinorhodin (Act) and the red undecylprodigiosin (Red). The annotated genome sequences of several other species have also been completed more recently: notably that of *S. avermitilis*, producer of the potent anthelmintic secondary metabolite avermectin; *S. scabies*, a plant pathogen, *S. clavuligerus*, a β -lactam producer, *S. venezuelae*, producer of chloramphenicol, and *S. griseus*, a producer of streptomycin (information on these genomes can be accessed at <http://streptomyces.org.uk>). These add to an impressive array of different actinomycete genomes that have been fully sequenced and which can be openly accessed. Comparative genomics offers unprecedented insight into both the shared aspects of actinomycete biology, and also the plethora of conditionally adaptive functions that *Streptomyces* in particular possess.

This article reviews many intriguing aspects of streptomycete biology. More detailed coverage of the historical perspectives and recent advances in *Streptomyces* research can be found in two books (Dyson, 2011; Hopwood, 2007); in addition, recent reviews on certain topics are cited in this article.

The Genome

Base Composition

The actinomycetes in general, and *Streptomyces* in particular, have DNA with an unusually high G + C content. For streptomycetes, with 73% G + C, this is close to the theoretical limit for coding conventional proteins. One consequence is that certain AT-rich codons are very rare, which can have implications for gene expression. In particular, there is a biological relevance for expression of genes involved in differentiation: genes necessary for vegetative growth lack the rare TTA leucine codon. Mutation of the cognate tRNA gene, *bldA*, prevents progress from the vegetative stage of the life cycle, blocking aerial development and antibiotic production. This is a consequence of the inability to translate the mRNAs of key developmental genes containing the rare codon.

Host DNA modification enzymes equivalent to the Dam and Dcm methylases of *Escherichia coli* do not appear to have a significant role in *Streptomyces*. Site-specific methylation of adenine or cytosine residues is related to the various restriction-modification systems found in members of the genus. A novel sulfur-containing base modification, due to phosphorothioation of guanine, has been

[☆]Change History: July 2014. P Dyson modified the Abstract, made changes in Sections 'Plasmids'; 'Hyphal Growth and Cell Division'; 'Primary Metabolism'; 'Regulation of Secondary Metabolism'; 'Secondary Metabolism'; and 'Regulation of Secondary Metabolism', and revised Figure 2.

This article is an update of P. Dyson, *Streptomyces*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 318–332.

Figure 1 The streptomycete life cycle illustrated by that of *S. coelicolor*. After dispersal, in favorable conditions, a spore (A) can germinate (B). Fluo-vancomycin staining of an emerging germ-tube (B1) reveals that synthesis of new peptidoglycan, and hence cell growth, occurs primarily at the tip. A substrate mycelium grows by tip extension and sub-apical branching (C): fluo-WGA (wheat germ agglutinin) staining reveals infrequent cross-wall formation in the substrate mycelium (C1). Atomic-force microscopy (AFM) reveals that the surface of substrate hyphae is relatively smooth (C2), without the decoration that is characteristic of aerial hyphae. Moreover an extracellular matrix is deposited as the tip grows, allowing the hyphae to adhere to the substrate. Growth of an aerial hypha is away from the nutrient source (D), fuelled in part by cannibalization of the substrate hyphae; antibiotic biosynthesis at this stage in development is believed to protect the nutrients released by breakdown of the substrate mycelium from other competing microorganisms. Young aerial hyphae are decorated with an irregular fibrous layer (AFM image, D1) specified by chaplin and rodlin genes. After growth cessation, the aerial hyphae differentiate to form spore chains (E). This involves highly coordinated multiple septation, revealed by fluo-WGA staining (E3), and by the appearance of regular-spaced spore compartments revealed by AFM (E1). The surface of the spore-compartments consists of a dense layer of well-organized fibers specified by the chaplin and rodlin genes (AFM image, E2). Older spores have characteristic surface concavities (AFM image, E4), indicating dehydration and loss of turgor.

discovered in a few members of the genus, including *S. lividans* and *S. avermitilis*. Subsequent to its discovery in these species, it has also been found in the DNA of several other non-streptomycete bacteria from diverse habitats and appears to be specified as part of a genetic island that has spread between these species. The biological significance of this modification is at present unknown.

The Chromosome

Streptomyces spp. characteristically possess a single large linear chromosome. The linear topology is unusual even among the actinomycetes, and is discussed in more detail below. The chromosome of *S. coelicolor* is 8.7 Mb, that of *S. avermitilis* 9.0 Mb, and *S. scabies* 10.1 Mb in size. The origin of chromosomal replication, *oriC*, and linked *dnaA* gene, are located in a central position. The coding density is largely uniform across the chromosome, with only a slight decrease in the distal regions, or chromosome arms. A central 'core,' comprising approximately half the total size of the chromosome, contains nearly all the genes that are likely to be unconditionally essential for growth. These include genes for cell division, DNA replication, transcription, translation and amino acid biosynthesis. This core region shares considerable synteny with the whole (circular) genomes of other actinomycetes such as those of *M. tuberculosis* (4.4 Mb) and *C. diphtheriae* (2.5 Mb), suggesting a common ancestry of primary cellular functions among actinomycetes. In contrast, the chromosome arms of *Streptomyces* genomes, consisting largely of 'conditionally adaptive' loci coding for probable non-essential functions such as an extensive array of hydrolytic enzymes and, to some extent, secondary metabolism, have either been acquired subsequent to divergence of *Streptomyces* from a common ancestor, or have been lost in actinomycetes with more specialized lifestyles. Closer examination of elements within the arms is consistent with an acquisition model, with evidence of integration of mobile DNA (transposable elements and plasmids) in these regions. In addition, corresponding genes shared between streptomycete genomes tend to occupy the core, whereas the arms contain non-orthologous genes, again consistent with gene acquisition, with the arms a potential 'playground' for evolution of novel attributes permitting a particular species to compete in its ecological niche.

The two ends of the chromosome consist of terminal inverted repeats (TIRs) that, depending on the species, can vary from less than 1 kb to more than 550 kb in size. A 170-bp region at the extremity of each TIR contains an array of tightly organized palindromic sequences that could permit the adoption of secondary structure in a single-stranded molecule. While this may have functional significance, in double-stranded DNA these palindromes are bound by a Telomere-associated protein (Tap) that is necessary for recruitment of Terminal Protein (TP), forming a complex needed for 'end-patching': limited DNA synthesis that completes chromosome replication.

Chromosome circularity is the norm among prokaryotes and it avoids the problem of replicating the ends of a linear molecule. This arises as DNA polymerases can extend a new DNA strand only in the 5' to 3' direction by adding nucleotides one at a time to an existing 3' -OH end. This end is provided by a short RNA primer that is subsequently removed, leaving a gap that is then filled in. Gap filling is primed from the 3'-end of an adjacent DNA strand. The problem with linear molecules is that an RNA primer cannot be synthesized opposite the extreme 3'-end of the template strand, and, even if a suitable complementary RNA primer could be synthesized from an internal template and then base-pair with the 3'-end, its subsequent removal would leave a gap which could not be filled as there is no priming strand. To account for this, small linear genomes such as that of *Bacillus* phage Φ 29 and adenoviruses initiate replication from either end using a TP bound to their free 5'-ends to prime synthesis. *Streptomyces* combine typical prokaryotic bidirectional chromosomal replication initiated from *oriC*, together with end-patching initiated from their TPs.

With a virtual absence of essential cellular functions coded by the chromosome arms, these extremities can in certain circumstances be dispensed with. Survival of spontaneous mutants with extensive deletions of terminal sequences may be a particular feature of laboratory grown cultures nurtured in a non-hostile environment. Progressively large deletions (hundreds of kilobases) extend into the arms from the ends. In a well-documented example, approximately 0.5% of spores of *S. lividans* give rise to variants lacking one chromosomal end, including a gene conferring resistance to the antibiotic chloramphenicol. This instability may be due to problems of orchestrating segregation of chromosomes when a multigenomic aerial hypha differentiates into a chain of unigenomic spores. The frequency of this genetic instability in the wild-type can be enhanced to 20% in *ftsK* mutants, probably due to incomplete segregation of chromosomes during sporulation septation: replication-terminal sequences may be trapped by in-growing septa in a compartment adjacent to that containing the chromosome core (see Sections 'Plasmids' and 'Hyphal Growth and Cell Division' for accounts of FtsK function and cell division, respectively). Initial spontaneous mutants also exhibit enhanced instability, possibly due to loss of *cis*-acting terminal sequences that are necessary for correct chromosome segregation, and up to 25% of segregants have an even larger chromosomal deletion spanning the *argG* gene (one of the few essential genes located in the arms). The deletion end-point is often a 5.7-kb tandemly amplified DNA element that exists as a duplicated element in the progenitor genome. In unstable mutants, this element exists as several hundred copies, maintained in the absence of any overt selection pressure, perhaps buffering any further deletions that could affect the integrity of the shortened chromosome. The relatively high instability of genes in the chromosome arms could provide a selection pressure to maintain essential genes within the core region, and, at the same time, contribute to rapid evolution of new functions encoded by the arms.

Plasmids

Scrutiny of *Streptomyces* genome sequences indicates that plasmids have played an important role in chromosome evolution, especially of the arms, with evidence of past integration events. In addition, there is a body of experimental evidence pointing to dynamic interactions between autonomous plasmids and the chromosome. *Streptomyces* plasmids are unusually diverse entities: they differ in terms of size, copy-number, topology and autonomy. There are small, covalently closed circular (ccc) high copy-number plasmids, larger ccc low copy-number plasmids, ccc plasmids that arise by reversible site-specific recombination from the chromosome, and linear plasmids that share features of the chromosome: a centrally-located origin of replication and TIRs with bound TPs to prime end-patching. A property common to maybe all is their self-transmissibility and ability to mobilize chromosomal DNA, making them supremely important in promoting genetic exchange and streptomycete evolution. The frequency of plasmid transfer between strains can approach 100%, and is apparent in laboratory conditions by the formation of 'pocks' on a lawn of recipient bacteria. These pocks are zones of (so far unexplained) retarded development surrounding the primary site of plasmid transfer: the retarded development is a consequence of intrahyphal spread of copies of the newly transferred plasmid.

The conjugation mechanism is quite unlike that of enteric bacteria such as *E. coli*. For the latter, conjugation depends on the function of more than 30 genes (e.g., the transfer region of the F-plasmid). In contrast, a single *tra* gene is responsible for the transfer of circular streptomycete plasmids (e.g., pIJ101, pSN22, pSG5, SCP2 and pSAM2). In addition, 'spread' genes (*spd*) promote subsequent intrahyphal spread, leading to the appearance of pocks. The F-plasmid *E. coli* paradigm involves transfer of a single DNA strand from donor to recipient after the two strains have been temporarily united via the sex-pilus, processes specified by the more than 30 F-plasmid *tra* genes. In *Streptomyces*, plasmid transfer is likely to be initiated by the fusion of donor and recipient hyphae growing together, perhaps promoted by plasmid functions: certain plasmids, such as the linear SLP2 of *S. lividans*, encode a muramidase-like function that could remodel the peptidoglycan of the fusing hyphae. For other plasmids this may be unnecessary: the TraB protein of pSG5 localizes to growing hyphal tips, where peptidoglycan is constantly being remodeled as a part of the growth process of hyphal extension (Section 'Cell Biology'). The streptomycete plasmid TraB proteins belong to the same family as FtsK, first characterized in *E. coli* as being involved in chromosomal DNA segregation at cell division. FtsK is assembled as a multimeric ring with a hole as an integral part of the septum formed during cytokinesis. Two DNA double helices are accommodated in the hole as FtsK pumps a looped circular double-stranded chromosomal DNA molecule between compartments in an ATP-dependent manner. The emerging evidence is that *Streptomyces* plasmid TraB proteins also hydrolyse ATP as they transfer double-stranded DNA between hyphae. Similar to FtsK, the TraB proteins also have a membrane-spanning domain that could promote the fusion of membranes necessary for interhyphal DNA transfer. The purified TraB protein of pSVH1 binds non-covalently, probably as multimers, to 8 bp repeats of a specific plasmid sequence, *clt*: this binding presumably permits specific transfer of the plasmid, but there is no DNA processing (e.g., nicking) during conjugal transfer as is necessary for single-stranded F-plasmid transfer between *E. coli* strains.

The mobilization of chromosomal DNA during the transfer of plasmids is thought to depend on a given TraB protein recognizing 8 bp sequences in the chromosome that are similar to the respective plasmid *clt* sequences: bioinformatic analysis indicates 23 regions containing repeats of the *clt* sequence recognized TraB encoded by pSVH1 in the *S. coelicolor* chromosome.

Cell Biology

Hyphal Growth and Cell Division

Streptomyces grow by hyphal tip extension and sub-apical branching (Figure 1; reviewed by Flardh, 2003). Most *de novo* cell wall synthesis is at the tips, rather than by insertion of new murein into the lateral walls. Cross-wall formation in the feeding substrate

hyphae is relatively infrequent and a sub-apical cell separated from the tip compartment by such a cross-wall can only grow once it has created a new tip by lateral branching. Tip growth contrasts markedly to the paradigm in rod-shaped bacteria such as *E. coli* and *B. subtilis*, which grow by intercalation of new murein into lateral walls, not into the cell wall surrounding the poles: the cell wall material of polar caps is inert after its initial synthesis during cell division. Apical extension in *S. coelicolor* involves assembly of a multiprotein 'tip-organizing center' involving Scy (*Streptomyces* cytoskeletal element), a unique bacterial coiled-coil protein with an unusual repeat periodicity, and DivIVA. The latter is essential for growth and its over-expression in preformed hyphae induces multiple branch-like lateral outgrowths, consistent with a role in stimulating tip growth. Interestingly, rod-shaped actinomycetes such as corynebacteria grow by apical extension at both poles, suggesting that apical growth may be conserved among members of the taxon. Again, in these bacteria, DivIVA localizes to the poles and is implicated in control of apical growth. In *S. coelicolor*, another cytoskeletal coiled-coil protein, FilP, also interacts with both Scy and DivIVA. FilP forms filaments along the hyphae and is considered to organize cell shape. Tip growth is regulated by a serine/threonine kinase, AfsK, that phosphorylates DivIVA causing it to disassemble from the tip-organizing center. This same kinase is also involved in the regulation of antibiotic production (Section 'Regulation of Secondary Metabolism').

In a non-actinomycete such as *B. subtilis*, DivIVA localizes to the poles but has an entirely different function in that it sequesters two proteins, MinC and MinD, which function as cell division inhibitors. Largely due to the localisation of these proteins to the pole regions, vegetative septation is confined to the mid-cell in *Bacillus*. These cell division inhibitors and their mode of action appear to be ubiquitous among bacteria, with a notable exception being the actinomycetes that lack a bona fide Min system. This introduces the intriguing question of how septa are positioned in actinomycetes in general and in *Streptomyces* in particular, in which different mechanisms may function in the substrate and aerial hyphae. A typical prokaryote mechanism for septum formation in *Streptomyces* (and other actinomycetes) is apparent from conservation of both the tubulin homologue FtsZ, which polymerises into the cytokinetic Z-ring, and several membrane proteins involved in linking the Z-ring to synthesis of septal peptidoglycan. A single *ftsZ* gene is required for two types of septation in *S. coelicolor*: infrequent cross wall formation that separates non-detached syncytial cells in the vegetative mycelium, and the multiple synchronous septation of the apical compartments of aerial hyphae that leads to the formation of unigenomic spores that ultimately separate from each other (Figure 1, panels C1 and E3). These developmentally distinct types of cell division are in part a consequence of how the *ftsZ* gene is regulated: there are two promoters, one of which is specifically activated in the aerial hyphae. In addition, the isolation of a missense mutation in *ftsZ* that preferentially affects sporulation septation indicates that there are differences in Z-ring assembly between vegetative and sporogenic hyphae. The synchronous formation of regularly spaced septa in the latter is particularly intriguing: not only is there an absence of the Min system to guide Z-ring formation, but also nucleoid occlusion, which affects the formation of Z-rings in *E. coli* and vegetative cells of *B. subtilis*, appears to have little influence in *Streptomyces*. The early stages of sporulation septation in *Streptomyces* often occur over non-segregated chromosomes, and separation of nucleoids is not observed until septal constriction has started. Emerging evidence points to novel ways by which cytokinesis in the aerial hyphae is regulated. A new family of SsgA-like proteins (SALPs), unique to sporulating actinomycetes, plays an important role in coordinating sporulation-specific cell division after growth arrest of the aerial hyphae. *S. coelicolor* possesses seven different SALPs, of which four are common to other streptomycetes. Unusually, these proteins have no motifs resembling those of known proteins. Each SALP is believed to have a specific role in the sequence of events from septum site selection to eventual spore separation, influencing peptidoglycan remodeling at the various stages, perhaps by interaction with penicillin binding proteins and autolysins. For example, SsgG is required for regular septum formation while chromosomes are being segregated into individual pre-spore compartments.

During hyphal growth, replication of the chromosome occurs asynchronously in many compartments. The highest replication activity occurs in the apical compartments of the presporogenic aerial hyphae. Orchestrating DNA segregation during sporulation appears to be an active process involving FtsK (Section 'The Chromosome'), ParA, a cytoskeletal protein that forms ATP-dependent polymers, and ParB, a DNA-binding protein. The latter binds to a set of 20 *parS* sites within 200 kb of the *S. coelicolor* *oriC* to form a massive nucleoprotein complex. These complexes are regularly spaced along the aerial hyphae immediately prior to multiple septum formation, indicating a role in accurate partitioning of chromosomes into eventual spore compartments. Aberrant DNA segregation is apparent in more than 10% of the spores of *S. coelicolor* *par* mutants. ATP-dependent polymerization of the cytoskeletal protein, ParA, is required to position the newly replicated origin-proximal region of the chromosome via interaction with ParB complexes assembled on *parS* sites. This positioning helps to ensure the accurate and synchronized segregation of DNA is the chromosome into individual prespore compartments. Another important player in this active segregation of DNA is the actin-like protein MreB that is localized to the inner face of developing spore walls. Among actinomycetes, *mreB* occurs only in genera that grow sporulating aerial hyphae and is specifically required for formation of normal spores and DNA segregation in *S. coelicolor*. The same protein also has a role in DNA segregation in some other non-actinomycetes such as *B. subtilis* and *Caulobacter crescentus*, which also divide to produce daughter cells with different developmental prospects, but not in *E. coli*, where all daughter cells are equivalent.

ParB chromosome complexes are also observed in the tips of the vegetative hyphae, suggesting that active partitioning may be important for DNA segregation into newly formed hyphal branches. Moreover, the tip-organizing center protein Scy recruits ParA to the hyphal tips and regulates ParA polymerization. However, no abnormalities in vegetative growth of *S. coelicolor* *par* mutants have been observed, perhaps indicating that in the absence of an active partitioning mechanism a passive process can substitute, especially given the relatively infrequent formation of cross-walls in the feeding hyphae. This is itself in part due to the low level of *ftsZ* expression. Frequent septation in sub-apical compartments of aerial hyphae is inhibited by expression of a small membrane protein, CrgA, that has a predicted 'hairpin' topology and functions to prevent Z-ring formation. *crgA* homologues

are ubiquitous but unique to the genomes of actinomycetes (sporulating and non-sporulating), where the gene is located in a conserved morphogenetic gene cluster. During aerial hyphal growth, when *ftsZ* expression (and possibly expression of other cell division genes) is developmentally up-regulated, Z-ring formation extends into sub-apical compartments of the aerial hyphae of a *S. coelicolor* *crgA* mutant. Conversely, when *crgA* is ectopically expressed in the aerial hyphae, Z-ring formation is inhibited and FtsZ is degraded: the resulting hyphae remain syncytial and are unable to produce spores. The conserved *crgA* gene cluster contains an essential *rodA* gene, probably involved in controlling hyphal extension. It is notable that while many cell division genes are essential in unicellular bacteria, they are dispensable in *Streptomyces* (although cell division mutants are often defective in sporulation). As a consequence, streptomycetes are attractive model systems to dissect the actinomycete cell division apparatus in more detail.

Morphological Differentiation

The erection of spore-bearing aerial hyphae is a way for non-motile streptomycetes to meet the challenges of localized nutrient depletion or other types of deterioration of their immediate environment: the spores can be dispersed to more favorable locations (reviewed by Flardh & Buttner, 2009). The aerial hyphae are quite distinct from the substrate feeding hyphae: they grow away from any remaining nutrient source and whereas the surface of substrate hyphae is smooth and hydrophilic, the aerial hyphae are coated with a hydrophobic fibrous layer (Figure 1, panels D1 and E2). Elaboration of this layer is believed to help the hyphae breach surface tension at the aqueous-air interface, presumably repelling the hyphae from growing back into an aqueous phase once they have emerged into an air pocket in the soil, and provide the aerial filaments a measure of resistance to desiccation in the gaseous phase. In *S. coelicolor* at least two types of hydrophobic surface-active proteins contribute to formation of the layer: the chaplins consist of eight members, ChpA-H, that self-assemble into amyloid fibrils, and the rodlin proteins, RdlA and RdlB, are believed to organize chaplin fibrils into a stable rodlet layer. Recent atomic force microscopy studies have documented changes to the cell surface as aerial hyphae develop. ChpD-H are short proteins made up of a single chaplin domain but with no anchor to the cell wall. These form unstable fibers coating young aerial hyphae and are continuously shed as the hyphae grow. A more stable layer, believed to be comprised of fibers of the longer chaplins, ChpA-C, which have cell-wall anchors, and organized by the Rdl proteins, is apparent on the surface of older hyphae. This layer is transiently disrupted and then reformed during cell division and the formation of spore chains. Rodlin genes have been identified in a number of different *Streptomyces* species but are absent in *S. avermitilis* that produces longer fibers that coat its aerial hyphae, whereas its spores are relatively smooth. The chaplin genes are also characteristic of sporulating actinomycetes, but not non-filamentous species such as *M. tuberculosis*.

Streptomyces spp. employ another strategy to ensure the release of nascent aerial hyphae into the gaseous phase by synthesizing and secreting surfactant molecules. *S. coelicolor*, for example, produces the surfactant peptide SapB during growth and development on glucose-containing rich medium in the laboratory (although not when grown on other media). SapB is a lantibiotic-like peptide that can restore the ability of 'bald' mutants, blocked in the ability to initiate sporulation, to form aerial hyphae. It is derived from the *ramS* gene, itself part of the *ram* gene cluster. A 42-amino acid peptide product of translation of *ramS* is modified by dehydration and thioether formation, probably by RamC, which is similar to other lantibiotic modification enzymes, to generate preSapB. The *ramAB* genes, which encode components of an ABC transporter, are required for export of this molecule, during which the pre-leader sequence is removed to yield mature SapB. Expression of the *ramCSAB* operon is controlled by a response regulator, RamR, the product of the divergently transcribed *ramR* gene. Similar lantibiotic-like surfactant molecules are produced by other *Streptomyces* species.

A surprising revelation of actinomycete genome sequencing projects has been that many species inhabiting the soil possess gas vesicle (*gvp*) genes. These organelles have been studied extensively in planktonic cyanobacteria and halophilic archaea where they function to enable these bacteria to position themselves optimally in the water column. Although homologues of the eight essential *gvp* genes occur in duplicate in certain *Streptomyces* genomes (e.g., in *S. coelicolor* and *S. scabies*), or even triplicate in *S. avermitilis*, there is no evidence to suggest a similar function in actinomycetes; indeed typical gas vesicles have not been detected in these bacteria. A possibly significant difference in structure and function may be attributable to the major envelope protein GvpA of actinomycetes that has a long C-terminal extension. It has been suggested that a novel role of the gas vesicle proteins in *Streptomyces* may be to aid the aerial hyphae in breaking through the water-air interface in certain conditions, based on the 'normal' activity of GvpA in creating a stable gas-water interface. Alternatively, novel actinomycete gas vesicles may function as turgor sensors. Maintaining turgor pressure may be vital for the erection of aerial hyphae; a *S. coelicolor* double *gvp* mutant is compromised in its ability to grow aerial hyphae in high salt conditions. Much has yet to be learnt about the function of these genes in actinomycetes as there does not appear to be a correlation between their presence and the life-style of the organism: they are present in the unicellular animal pathogen *Rhodococcus equi* but not in the filamentous saprophyte *Thermobifida fusca*, nor in unicellular pathogens such as *M. tuberculosis* and *C. diphtheriae*.

Metabolism

Primary Metabolism

Soil nutrient levels tend to be carbon-rich but nitrogen- and phosphate-poor, reflecting that the principle nutrient input is plant matter. The variety and multiplicity of carbohydrate catabolic pathways in streptomycetes reflects the diversity of soil-derived

carbohydrates. In their natural environment, streptomycetes feed by secreting complexes of hydrolytic enzymes. *S. coelicolor* has genes for 60 proteases/peptidases, 13 chitinases/chitosanases, 8 cellulases/endoglucanases, 3 amylases and 2 pectate lyases. Often, induction of a hydrolytic enzyme complex is coordinated by an inducer that is unrelated to the substrate or product of any particular enzyme in the complex; for example, a product of xylan catabolism can induce cellulase production. The converse to induction is carbon catabolite repression whereby specific metabolic processes are down-regulated, exemplified by glucose repression, in which the readily utilized glucose represses synthesis of enzymes needed to break down harder-to-use carbon sources. This is of particular interest in *Streptomyces* as it not only affects the utilization of various carbon sources, but also the synthesis of secondary metabolites (see Section 'Secondary Metabolism'). The mechanisms of glucose repression are different from the paradigm in enteric bacteria. For example, an ATP-dependent glucose kinase activity is required for glucose repression of many genes, and it has been suggested that glucose catabolites (e.g., fructose 1,6-biphosphate) mediate this effect. Glucose repression of other genes, for example, *chi63* encoding a chitinase in *S. coelicolor*, is independent of glucose kinase activity.

In *Streptomyces*, many steps in the glycolytic, pentose phosphate and TCA cycle pathways are represented by two or more forms, isoenzymes, possibly under differential regulation dependent on temporal and spatial cues and the nature of the primary carbon source. Most analysis has focussed on glucose metabolism as this is the common carbon source used in antibiotic fermentations. The Embden-Meyerhof pathway is the most important glycolytic pathway; it is used to generate ATP and also provide precursors for secondary metabolism. It is regulated primarily at the level of phosphofructokinase; in *S. coelicolor* there are three phosphofructokinase isoenzymes, although only one has a major role in glycolysis. The function of the other two isoenzymes is as yet unclear.

Given the variability of their natural habitat, which can include periods of flooding, it is perhaps not surprising that *Streptomyces* spp. can adapt to growth in anoxic conditions. Indeed, in standing liquid culture they form floating, differentiating colonies (although flotation is not dependent on functional *gvp* genes). In these conditions a steep oxygen gradient can result so that at a depth of approximately 1 mm the hyphae are growing under near anaerobic conditions. The genome sequence of *S. coelicolor* contains three operons that putatively each encode a typical four-subunit respiratory nitrate reductase. This protein is involved in anaerobic metabolism, indicating that *S. coelicolor* possesses enzymes to accommodate metabolism under anoxic or microaerobic conditions, as do pathogenic actinomycetes such as corynebacteria and mycobacteria. There is also evidence to indicate that *Streptomyces* spp. are capable of a mixed-acid type of fermentation in oxygen-limiting conditions: they have had to evolve a broad range of metabolic pathways to deliver sufficient energy to maintain the membrane potential, or to sustain growth, when oxygen gets depleted.

The soil is typically a nitrogen-poor environment and consequently many nitrogen catabolic pathways are constitutively expressed. In addition, there are few examples of feedback repression of amino acid biosynthesis, reflecting the nutrient-poor nature of soil. Amino acids are key precursors for the biosynthesis of many secondary metabolites and in some cases a duplicate set of biosynthetic genes is expressed specifically to provide substrates for secondary metabolism. An example is a second partial set of tryptophan biosynthetic genes located as part of the gene cluster for synthesis of calcium-dependent antibiotic (CDA) in *S. coelicolor*. In virtually all bacteria glutamine synthetase (GS) is a key enzyme in nitrogen metabolism and has dual functions in L-glutamine biosynthesis and nitrogen assimilation. In the biosynthetic reaction, glutamine synthetase catalyzes the ATP-dependent formation of L-glutamine from L-glutamic acid and ammonia. Assimilation of ammonium into cellular metabolism is governed by glutamine synthetase in concert with glutamate synthase in the GS/GOGAT pathway, which is ubiquitous in bacteria, yielding L-glutamine and L-glutamate, the key nitrogen donors for biosynthetic reactions. *S. coelicolor* possesses two types of glutamine synthetase: a prokaryotic GSI-beta-subtype enzyme (encoded by *glnA*) and a eukaryote-like glutamine synthetase II (encoded by *glnII*). This appears to be the case for other streptomycetes, but not mycobacteria. In *S. coelicolor* GSI and GSII are differentially regulated. In conditions of nitrogen limitation, *glnA* is constitutively expressed throughout the developmental cycle, whereas *glnII* transcription increases with the onset of morphological differentiation, and significant GSII activity is only detected in morphologically differentiating cells. Two unique OmpR-like regulators with disparate functional properties (GlnR and GlnRII) are involved in transcriptional control of GSI, GSII, and other nitrogen metabolism genes. GlnR is an activator of *glnA* transcription, whereas GlnRII may modulate expression of both genes (GlnR is also directly involved in regulation of antibiotic production; Section 'Regulation of Secondary Metabolism'). In nitrogen-rich conditions, GSI is post-translationally controlled via modification by an adenyltransferase homologous to GlnE from enteric bacteria. However, whereas this post-translational control in enterobacteria is dependent on components of the nitrogen-sensing Ntr system, in particular GlnK and GlnD, the orthologous proteins in *S. coelicolor*, exert no regulatory influence on GSI. Although the roles of GlnK and GlnD in the latter remain to be elucidated, it is noteworthy that in *S. coelicolor* GlnK is post-translationally adenylated by GlnD. In enterobacteria, GlnD modifies GlnK by uridylylation. Low GSII activity in *S. coelicolor* is in contrast to GSII activity in *S. viridochromogenes*, in which it constitutes up to 30% of the overall activity. This active GSII in *S. viridochromogenes* may have a special function, as this species produces the antibiotic phosphinothricin-tripeptide (PTT), an inhibitor of type I and type II glutamine synthetases. The PTT biosynthesis cluster includes the *pat* gene encoding an acetyltransferase, which inactivates the antibiotic, but additional resistance mechanisms may be advantageous to the producer. Resistance against PTT can be achieved by elevated levels of GS, which protect bacteria from the action of PTT: the increased activity of GSII in *S. viridochromogenes* may be part of the self-protection mechanism against PTT. It is thought that isoenzymes of primary metabolic enzymes are very often involved in antibiotic autoimmunity.

The importance of understanding nitrogen regulation in *Streptomyces* in more detail is underlined by the general repressive affects on antibiotic biosynthesis of having high ammonium concentrations in the growth medium. High inorganic phosphate (P_i) also negatively impacts on antibiotic biosynthesis: indeed nutritional limitation of P_i triggers antibiotic production, a condition that is

likely to equate to the soil environment. Our understanding of the physiological response to P_i limitation points to a critical role of intracellular ATP/ADP ratios. Phosphate metabolism is controlled by elements of the *pho* regulon, itself regulated by a two-component signal transduction system, PhoR-PhoP, that functions to promote adaptation to low P_i by increasing phosphate uptake and/or utilization of cellular polyphosphate reserves. The latter is mediated by polyphosphate kinase (PPK): expression of the *ppk* gene is up-regulated by the PhoP response regulator in P_i -limiting conditions. When the ATP/ADP ratio is high (P_i -sufficient conditions), PPK catalyzes the reversible polymerisation of the γ phosphate of ATP into polyphosphate. ATP is regenerated from polyphosphate by PPK when the ATP/ADP ratio falls. It has been suggested that in the absence or depletion of polyphosphate, central carbon metabolism is up-regulated in response to a low ATP/ADP ratio as another way to generate ATP: as this may coincide with the end of exponential growth, the products (reduced cofactors, ATP, carbon catabolites) will not be consumed in general anabolic reactions but can instead be utilized for the biosynthesis of secondary metabolites. The PhoR-PhoP system also regulates nitrogen assimilation as phosphorylated PhoP represses expression of *glnR* (PhoP also regulates antibiotic production; Section 'Regulation of Secondary Metabolism').

Secondary Metabolism

Secondary or specialized metabolites are defined as being produced by narrow taxonomic groups of organisms. They are typically non-essential for the producing organism and produced after the main phase of growth (although some are continuously produced during growth, for example chloramphenicol by *S. venezuelae*). They have diverse, unusual and often complex chemical structures. Usually, production of a given secondary metabolite is determined by a set of genes clustered together, arranged as a number of operons and single genes; these gene clusters range from a few to over 100 kb. The range of biological activities of streptomycete secondary metabolites is broad: some have inhibitory or microcidal activities against microorganisms (i.e., true antibiotics), others are toxic against metazoans, others have a hormone-like role in microbial differentiation, whereas some have a role in metal transport (blurring the distinction between primary and secondary metabolism). There are also many secondary metabolites with either no known biological activity or an activity demonstrated in the laboratory or clinic that is probably incidental to their function in the environment (e.g., vertebrate immunomodulators). The actinomycetes produce the greatest diversity, about two-thirds, of secondary metabolites, and *Streptomyces* spp. account for more than 70% of the actinomycete compounds discovered to date: consequently they are undeniably model systems to understand this aspect of biology.

To some extent the building blocks for assembling secondary metabolites are the products of primary metabolism (e.g., acetyl CoA, some amino acids). As noted above, however, with the example of the second *trpCDGE* operon located within the *cda* cluster, dedicated isoenzymes are also utilized to produce specific precursors. *S. coelicolor* possesses several *fabH* paralogs. One of these is essential and is part of the main fatty acid biosynthetic operon, coding for a dedicated ketosynthase required for the first step in fatty acid synthesis (primary metabolism). Two of the other *fabH* paralogs are in gene clusters for known secondary metabolites: the *red* and *cda* clusters. These two clusters determine production of antibiotics with fatty acid components: the presence of *fabH* homologues in these clusters indicates that rather than 'borrowing' the product of the ketosynthase from primary metabolism, each antibiotic gene cluster specifies a ketosynthase dedicated to production of the respective secondary metabolite.

The genome sequence of *S. coelicolor* has revealed 23 clusters of genes, representing about 4.5% of the genome, predicted to encode biosynthetic enzymes for secondary metabolites, only six of which had been identified pre-sequencing. The genome of *S. avermitilis*, previously known to produce melanin, oligomycin and avermectin, has 30 gene clusters (~6% of the genome) dedicated to biosynthesis of secondary metabolites. In both organisms, many of these clusters lie in the chromosome arms, consistent with a concept that the compounds may only be synthesized under certain growth conditions, as an adaptive response. Although at least three of the *S. coelicolor* clusters specify antibiotics, most of the others are probably responsible for products with different functions. For example, hopanoids may protect against water loss through the plasma membrane of aerial hyphae, and eicosapentaenoic acid may help to maintain membrane fluidity at low temperature. Three clusters code for siderophore biosynthesis, enabling the organism to scavenge iron from its extremely insoluble FeIII form in the environment. Consequently, many of the secondary metabolites may be termed 'stress metabolites,' enabling adaptation to physical and chemical stresses, and, in the case of antibiotics, permitting competition against rival soil microorganisms. A current challenge is to understand more about the regulation of biosynthesis of these products (see Section 'Regulation'), in particular how to turn on production of 'cryptic' pathways that could potentially augment the number of metabolites with useful pharmacological activities.

Another artificial strategy to extend the variety of secondary metabolites produced by the genus is to employ 'combinatorial biosynthesis' (reviewed by Baltz, 2006). Essentially this means genetically manipulating biosynthetic pathways, based on precise knowledge of the roles of individual enzymes or active sites within these proteins. This strategy has been applied to change the aglycone skeleton of metabolites produced by an 'assembly-line' process – non-ribosomally synthesized peptides and type I polyketides – both amenable to redesign, or to alter the pattern of glycosylation subsequent to synthesis of an aglycone. The polyketides encompass a very large and diverse class of streptomycete secondary metabolites. Indeed *Streptomyces* spp. have evolved three types of polyketide synthase (PKS): a type I PKS consists of multifunctional polypeptides that include different catalytic functions as separate domains, similar to vertebrate fatty acid synthases, whereas a type II PKS is a complex of several separate polypeptides, related in function to the fatty acid synthases of other bacteria and of plants. In bacteria, type III PKSs typically catalyze iterative decarboxylation and condensation reactions of malonyl-CoA building blocks in the biosynthesis of polyhydroxyaromatic products. The concept of combinatorial biosynthesis, first demonstrated with the genes for the Type II PKSs of actinorhodin and related compounds, was exploited for practical purposes by manipulating synthesis of the aglycone of erythromycin, a type

I polyketide produced by the actinomycete *Saccharopolyspora erythraea* (formerly *Streptomyces erythraeus*). The aglycone macrolide is synthesized by sequential condensation of propionate units in a process involving 28 active sites arranged along three giant proteins that comprise the PKS: as the polyketide chain grows it is passed processively along the assembly-line PKS. At the end of the assembly line, the polyketide is lactonised and the aglycone is then hydroxylated and glycosylated, involving 18 further proteins. Different aglycones can be derived by genetic manipulation to change individual steps along the assembly-line. These modifications can alter, for example, the number of propionate units assembled in the polyketide chain, substitution of other building units for propionate, or change the degree of reduction of a specific carbonyl group formed at a given condensation reaction.

These types of engineered changes to secondary metabolite structure supplement the natural variability in biosynthetic pathways that often result in several related molecules being determined by a single gene cluster. In combination with the presence in a single species of multiple gene clusters specifying the synthesis a variety of secondary metabolites of quite distinct chemical structures, the biosynthetic capacity of a streptomycete is remarkable. As indicated previously, a driving force for the evolution of this capacity is the diversity of function of different metabolites. In addition, there are examples of two structurally distinct secondary metabolites produced by a single species that function synergistically. An example is the coproduction by several species, the best studied of which is *S. clavuligerus*, of the β -lactam cephamycin C and the β -lactamase inhibitor clavulanic acid. This combination of a β -lactam antibiotic and a β -lactamase inhibitor is effective against β -lactam-resistant bacteria that could compete for the same ecological niche as *Streptomyces*. Another example concerning increased effectiveness of antibiotic activity is provided by producers of the streptogramins that inhibit bacterial protein synthesis by binding to the ribosome. All streptogramin producers, for example *S. pristinaespiralis*, produce two structurally distinct molecules: a type A and a type B streptogramin, determined by two different gene clusters. Whereas type A or type B streptogramins alone are bacteriostatic, the combination is bacteriocidal. This is due to synergistic binding to the ribosome: binding of the type A antibiotic is thought to change the conformation of the ribosomal RNA to expose a high-affinity binding site for the type B compound. Both these examples of synergy have been clinically exploited in the formulation of effective combination drugs: Augmentin is a combination of the unnatural β -lactam amoxicillin with natural clavulanic acid, and Synercid is a combination of semi-synthetic type A and type B streptogramins.

Many of the gene clusters determining antibiotic production contain one or more cluster-specific regulatory (CSR) genes encoding transcriptional activators. Expression of these genes is itself coordinated by pleiotropic regulatory networks (see Section 'Regulation') that integrate information about cell physiology and environmental conditions to ensure that an antibiotic is produced in a highly regulated manner. The cluster-specific regulators activate expression of the cognate biosynthetic genes and also antibiotic self-resistance genes contained within the clusters. The products of these resistance genes can protect antibiotic producers by a variety of mechanisms, including modification of the antibiotic target and by active efflux of the drug. Interestingly, the primary transcripts of several self-resistance genes lack untranslated leader sequences – the start-points for transcription and translation are coincident; the significance of this in relation to ribosome recognition and control of translation is as yet unclear. The architecture of antibiotic biosynthetic gene clusters allows for coordinated regulation of biosynthesis and resistance, and this can clearly facilitate horizontal transfer of entire clusters to other species via mechanisms such as conjugal transfer (Section 'Plasmids'). An example of this coordinated regulation is the induction of resistance involving active efflux of Act by *S. coelicolor*: the inducer is an inactive precursor of the antibiotic, ensuring that resistance is established before the antibiotic accumulates to a toxic level.

Due to the extensive background knowledge concerning antibiotic production by *S. coelicolor*, it is an attractive 'chassis' for expressing heterologous secondary metabolite gene clusters. With this in mind, strains have been specifically developed for this purpose. As existing endogenous pathways can compete with introduced pathways for the precursor compounds supplied by primary metabolism, genome-reduced strains have been derived lacking the linear plasmid SCP1 that carries the methylenomycin biosynthetic gene cluster and also chromosomal Act, Red, CDA and CPK clusters. Deletion of these pathways also facilitates identification of a new product as the strain has a much simplified extracellular metabolome. In addition, antibiotic production-promoting *rpoB* (RNA polymerase) and *rpsL* (ribosomal protein S12) mutations have been introduced. These strains support high levels of production of a wide range of secondary metabolites.

Transport in and out of the Cell

Transport is an important aspect of streptomycete biology, enabling many interactions between the bacteria and their complex soil environment. *S. coelicolor* has 614 proteins with predicted transport function. The largest number is of the ABC transporter type predicted to be involved in either import or export of molecules, including sugars, amino acids, oligopeptides and ions. Import is believed to be facilitated by 75 putative surface-anchored substrate-binding proteins. Several ABC transporters that function as specific antibiotic efflux pumps have been identified in a number of species. For example, secretion and self-resistance to oleandomycin by *S. antibioticus* is mediated by the OleB ABC transporter, and in *S. argillaceus* an ABC transporter and an integral membrane protein encoded by the *mtrA* and *mtrB* genes are responsible for export and self-resistance to the anthracycline antitumour antibiotic mithramycin. Whereas the ABC transporters are multicomponent proteins that bind and facilitate transport by ATP hydrolysis, other single component transporters effect transport of small solutes in response to chemiosmotic ion gradients. The latter are also employed for self-resistance and efflux of antibiotics, examples being the product of the *mmr* gene that is part of the methylenomycin biosynthetic gene cluster encoded by a large linear plasmid of *S. coelicolor*, and the multidrug efflux pump protein encoded by the *cmcT* gene in the cephamycin cluster of *S. clavuligerus*.

The saprophytic lifestyle of *Streptomyces* depends on secretion of a plethora of hydrolases: *S. coelicolor* has 100 predicted secreted hydrolases out of a total of 819 potentially secreted proteins. As in most bacteria, the general secretory pathway (Sec) is the

predominant route for protein export, whereby proteins are translocated across the membrane in an unfolded state through a membrane-embedded translocon, to which they are targeted by cleavable N-terminal signal peptides. However, an additional protein export pathway, designated Tat (for twin-arginine translocation), also functions in *Streptomyces*: indeed *in silico* predictions suggest that of all prokaryotes, *Streptomyces* spp. possess by far the largest number of Tat substrates (up to 189 of the 819 predicted secreted proteins of *S. coelicolor*). Proteins are targeted to the Tat pathway by tripartite N-terminal signal peptides that contain a conserved twin-arginine motif. Importantly, the Tat pathway transports only prefolded protein substrates and in *E. coli* the system is used to secrete prefolded proteins associated with cofactors. Of the 189 predicted Tat substrates of *S. coelicolor*, so far 27 have been experimentally verified (comprising 30% of all detectable exported proteins). Of these, several are predicted to be involved in phosphate and carbohydrate metabolism, nutrient transport, and lipid metabolism. In contrast to the paradigm established with Tat substrates in *E. coli*, only 3 of the 27 *S. coelicolor* Tat-dependent proteins are likely to be cofactor-containing. Consequently, it appears that the Tat pathway in *Streptomyces* is a general protein export system responsible for secretion of a diverse range of proteins.

Compared to unicellular pathogenic actinomycetes such as *M. tuberculosis* and *C. diphtheriae*, *Streptomyces* spp. have a far greater capacity for transport, both in terms of the numbers of predicted secreted proteins and the numbers of transporters, undoubtedly reflecting their free-living lifestyle and the importance of interactions with a highly variable environment.

Regulation

The proportion of regulatory genes increases in relation to bacterial genome size. *Streptomyces* spp, with some of the largest prokaryote genomes, combined with their need to adapt their physiology and cell biology to varying environmental conditions, possess an enormous capacity for regulation. A total of 965 proteins (12.3%) encoded by the *S. coelicolor* genome are predicted to have regulatory function. There are 65 predicted sigma factors, 85 sensor kinases and 79 response regulators (including 53 sensor-regulator pairs), 44 serine/threonine protein kinases, and >100 DNA binding proteins belonging to different regulator families. Recent evidence suggests that *Streptomyces* spp. also have the ability to modify local chromatin structure according to their growth conditions, although it is too early to predict whether these dynamic changes to nucleoid structure influence or reflect patterns of gene expression.

Alternative Sigma Factors

Sigma factors act by binding to and influencing the promoter specificity of the RNA polymerase core enzyme, thereby directing selective transcription of different gene sets, coordinating gene expression in response to various environmental and endogenous cues. Phylogenetic comparison of streptomycete sigmas indicates that they belong to 4 groups. *S. coelicolor* possesses a single group 1 'housekeeping' sigma (HrdB), 3 group 2 sigmas (HrdA, C, D), 10 group 3 sigmas, and 45 group 4 (extracytoplasmic function, or ECF) sigmas. As a *hrdACD* triple mutant lacks any obvious phenotype, the function of the group 2 sigmas is unknown. At least 2 group 3 sigmas regulate developmental events after emergence of aerial hyphae, culminating in spore formation (Sections 'Hyphal Growth and Cell Division' and 'Regulation of Development'). This sporulation programme begins, before sporulation septation, with σ^{WhiG} , and ultimately leads to expression of the late spore-specific sigma, σ^{F} (Figure 2). The *sigF* gene is not transcribed until after the sporulation septa are formed. σ^{F} is required for expression of the *whiE* gene cluster specifying a type II polyketide synthase responsible for synthesis of the gray spore pigment. Two of the other group 3 sigmas, σ^{H} and σ^{B} , have dual roles: they have been implicated in controlling proper differentiation and, together with another group 3 sigma, σ^{I} , they are also involved in osmotic stress responses (Figure 2). Indeed, σ^{H} is also involved in a temperature stress response. As sporulation is itself a stress response by non-motile streptomycetes, this overlap in function is perhaps not unexpected. The activities of some of these group 3 sigmas are regulated by interaction with anti-sigma factors. For example, σ^{B} is activated by interaction of its anti-sigma factor RsbA with an anti-anti-sigma factor RsbV.

Only a few of the 45 group 4 (ECF) sigmas have been studied thus far. σ^{BldN} is required for formation of aerial hyphae (Figure 2). Transcription of its gene is repressed by the transcription factor BldD, which also represses transcription of *whiG*. In addition, activation of σ^{BldN} is believed to require proteolytic cleavage of a ~90 amino acid N-terminal extension that may anchor the inactive sigma factor to the membrane. σ^{U} indirectly affects aerial development as well. Overexpression of σ^{U} or eliminating its cognate antisigma factor RsuA causes a delay in the growth of aerial hyphae. A mutant with both the sigma factor and anti-sigma factor genes deleted develops normally, indicating that uncontrolled activity of σ^{U} causes the developmental phenotype. The group 4 σ^{E} is activated by cell wall stress and regulates, in turn, genes involved in cell wall integrity. The sigma factor gene is part of an operon that also specifies a two-component sensor-regulator gene pair. When activated, the histidine protein kinase, CseC, phosphorylates the response regulator, CseB, which in turn activates transcription of the operon.

At least one other group 4 sigma, σ^{R} , and possibly σ^{T} as well, respond to cytoplasmic oxidative stress. σ^{R} transcribes an operon encoding both thioredoxin and thioredoxin oxidase: together, these proteins reduce disulphide bonds formed in proteins under oxidizing conditions. In reducing conditions, σ^{R} is bound by its anti-sigma factor, RsrA. This is relieved in oxidizing conditions because of disulphide bonds formed between several cysteine residues in RsrA, causing release of the sigma factor. RsrA was the first example of a new family of zinc binding anti-sigma factors subsequently discovered in many other bacteria. In *M. tuberculosis*, the corresponding proteins, σ^{H} and RshA, regulate responses to both oxidative stress and heat shock.
